Experimental studies of canine large intestinal IBD have shown that many of the clinical signs (diarrhea, passage of mucus and blood, abdominal pain, tenesmus, and urgency of defecation) are related to motor abnormalities of the colon. Ethanol and acetic acid perfusion of the canine colon induces a large bowel form of IBD syndrome indistinguishable from the natural condition.[165,166] Inflammation in this model suppresses the normal phasic contractions of the colon, including the migrating motility complex, and triggers the emergence of GMCs. The appearance of these GMCs in association with inflammation is a major factor in producing diarrhea, abdominal cramping, and urgency of defecation. GMCs are powerful lumen-occluding contractions that rapidly propel pancreatic, biliary, and intestinal secretions in the fasting state (and undigested food in the fed state) to the colon to increase its osmotic load.[43,45,46] Malabsorption results from direct injury to the epithelial cells and from ultrarapid propulsion of intestinal contents by GMCs so that sufficient mucosal contact time is not allowed for digestion and absorption to take place.

Figure 223-8 Immunopathology of canine large bowel inflammatory bowel disease (IBD) and canine ulcerative colitis. IBD of the canine colon may be more of a Th1-type response, whereas ulcerative colitis is more a Th2-type response. *MHC,* Major histocompatibility complex; *APC,* antigen-presenting cell; *IL,* interleukin; *IFN,* interferon; *TNF,* tumor necrosis factor.

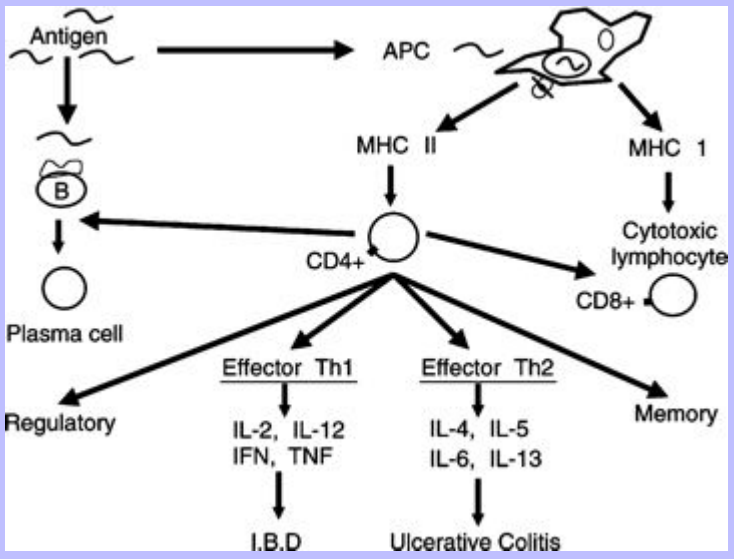

Table • 223-5 Immunologic and Motility Abnormalities in Canine Large Bowel Inflammatory Bowel Disease

HISTOLOGIC FINDINGS	IMMUNOLOGIC ABNORMALITIES	REFERENCE
Lymphocytic-plasmacytic colitis	Increased nitric oxide and IgG in colonic lavage fluid	162
Lymphocytic-plasmacytic colitis	Increased expression of inducible nitric oxide synthase mRNA	164
Lymphocytic-plasmacytic colitis	Increases in T cells and B cells in lamina propria	36
Lymphocytic-plasmacytic colitis	Increases in CD3+T cells and in IgA+and IgG+plasma cells	163
Lymphocytic-plasmacytic colitis	Increased IL-2 and TNF-αmRNA expression	160
TISSUE/CELL TYPE	**MOTILITY ABNORMALITIES**	**REFERENCE**
Colon	Loss of spontaneous phasic contractions	165,166
	Decreased frequency of migrating motor complexes (MMCs)	165,166
	Increased frequency of giant migrating contractions (GMCs)	165,166
Colonic circular smooth muscle cells	Decreased amplitude and duration of the slow wave plateau potential	167
	Shift from the M3 to M2 muscarinic receptor subtype	169
	Reduced calcium influx through L-type calcium channel	170
	Reduced L-type calcium channel expression	171
	Decreased open probability of KCa channels	172
	Down-regulation of PKC α, β, ϵ, expression and activation	174
	Reduced phospholipase A2 expression	173
	Increased NF-κB expression and activation	175
Colonic enteric neurons	Sensitization to substance P during colonic inflammation	168
Colonic interstitial cells of Cajal	Reduced density of interstitial cells	167
	Cytoplasmic vacuolation and damage to cellular processes	167

IgG, Immunoglobulin G; *IgA,* immunoglobulin A; *IL-2,* interleukin-2; *TNF-α,* tumor necrosis factor alpha; *PKC,* protein kinase C; *M,* muscarinic; *NF-κB,* nuclear factor-κB; *KCa,* calcium-activated potassium channel.

Inflammation impairs the regulation of the colonic motility patterns at several levels (i.e., enteric neurons, interstitial cells of Cajal, circular smooth muscle cells; summarized in Table 223-5). Inflammation-induced changes in the amplitude and duration of the smooth muscle slow wave plateau potentials contribute to the suppression of RPCs.[165] These alterations likely have their origin in structural and functional damage to the interstitial cells of Cajal.[167] At the same time that inflammation suppresses the RPCs, inflammation sensitizes the colon to the stimulation of GMCs by the neurotransmitter substance P.[168] These findings suggest that SP increases the frequency of GMCs during inflammation and that selective inhibition of GMCs during inflammation may minimize the symptoms of diarrhea, abdominal discomfort, and urgency of defecation associated with these contractions.[168]

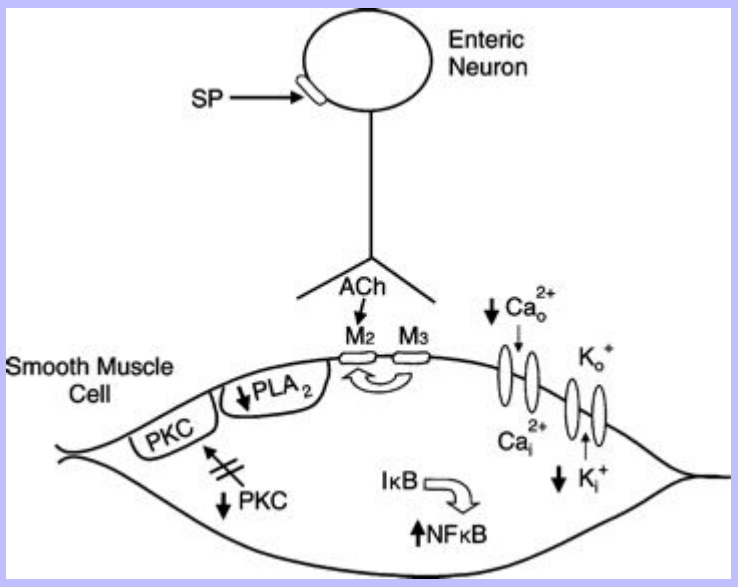
Inflammation suppresses the generation of tone and phasic contractions in the circular smooth muscle cells through multiple molecular mechanisms (see Table 223-5; Figure 223-9). Inflammation shifts muscarinic receptor expression in circular smooth muscles from the M_3 to the M_2 subtype.[169] This shift

has the effect of reducing the overall contractility of the smooth muscle cell. Inflammation also impairs calcium influx[170] and down-regulates the expression of the L-type calcium channel,[171] which may be important in suppressing phasic contractions and tone while concurrently stimulating GMCs in the inflamed colon. Changes in the open-state probability of the large conductance calcium-activated potassium channels (K_{Ca}) partially attenuate this effect.[172] Inflammation also modifies the signal transduction pathways of circular smooth muscle cells. Phospholipase A_2 and protein kinase C (PKC) expression and activation are significantly altered by colonic inflammation,[173,174] and this may partially account for the suppression of tone and phasic contractions. PKC α, β, and ε isoenzyme expression is down-regulated, PKC ι and λ isoenzyme expression is up-regulated, and the cytosol-to-membrane translocation of PKC is impaired.[174] The L-type calcium channel, already reduced in its expression, is one of the molecular targets of PKC. Inflammation also activates the transcription factor NF-κB that further suppresses cell contractility.[175]

223.5.1.8 Clinical Examination

The clinical signs of large intestinal IBD are those of a large bowel-type diarrhea (i.e., marked increased frequency, reduced fecal volume per defecation, blood pigments and mucous in feces, and tenesmus). Anorexia, weight loss, and vomiting are occasionally reported in animals with severe IBD of the colon or concurrent IBD of the stomach, small intestine, or both. Clinical signs usually wax and wane in their severity. A transient response to symptomatic therapy may occur during the initial stages of IBD. As the condition progresses, diarrhea gradually increases in its frequency and intensity and may become continuous. In some cases the first bowel movement of the day may be normal or nearly normal, whereas successive bowel movements are reduced in volume and progressively more urgent and painful. During severe episodes, mild fever, depression, and anorexia may occur.

Figure 223-9 Motility abnormalities in canine large bowel inflammatory bowel disease (IBD). Inflammation impairs motility by inducing changes in receptor, signal transduction, and ion channel activity in smooth muscle cells and enteric neurons. Changes include but not are limited to a shift in muscarinic receptor expression from M_3 to M_2 receptor subtype; impaired calcium mobilization; down-regulation of L-type calcium channel expression; changes in the open-state probability of the large conductance calcium-activated potassium channels (K_{Ca}), down-regulation of phospholipase A_2 and protein kinase C (PKC) α, β, and ϵ isoenzymes; and activation of the transcription factor NF-κB in smooth muscle cells. Inflammation also sensitizes the colon to the stimulation of GMCs by the neurotransmitter substance P. *PKC,* Protein kinase C; *PLA_2,* phospholipase A_2; *M,* muscarinic; *NF-κB,* nuclear factor-κB; *K_{Ca},* calcium-activated potassium channel; *SP,* substance P; *Ach,* acetylcholine.



There does not appear to be any sex predilection, but age may be a risk factor, with IBD appearing more frequently in middle-aged animals (mean age approximately 6 years with a range of 6 months to 20 years).[50,51] German shepherd and boxer dogs are at increased risk for IBD, and pure-breed cats appear to be

at greater risk. Cats more often have an upper GI form of IBD, whereas dogs are at risk for both small and large bowel IBD.

Physical examination is unremarkable in most cases. Thickened bowel loops may be detected during abdominal palpation if the small bowel is concurrently involved. Digital examination of the anorectum may evoke pain or reveal irregular mucosa, and blood pigments and mucous may be evident on the examination glove.

223.5.1.9 Diagnosis

CBCs, serum chemistries, and urinalyses are often normal in mild cases of large bowel IBD. Chronic cases may have one or more subtle abnormalities. One review of canine and feline IBD reported several hematologic abnormalities including mild anemia, leukocytosis, neutrophilia with and without a left shift, eosinophilia, eosinopenia, lymphocytopenia, monocytosis, and basophilia.[51] The same study reported several biochemical abnormalities including increased activities of serum alanine aminotransferase and alkaline phosphatase, hypoalbuminemia, hypoproteinemia, hyperamylasemia, hyperglobulinemia, hypokalemia, hypocholesterolemia, and hyperglycemia. No consistent abnormality in the CBC or serum chemistry has been identified.

A scoring index for disease activity in canine IBD was recently developed that relates severity of clinical signs to serum acute-phase protein (C-reactive protein [CRP], serum amyloid A) concentrations.[50] The canine IBD activity index (CIBDAI) assigns levels of severity to each of several gastroenterologic signs (e.g., anorexia, vomiting, weight loss, diarrhea), and it appears to be a reliable index of mucosal inflammation in canine IBD. Interestingly, both the activity index and serum concentrations of CRP improve with successful treatment, suggesting that serum CRP is suitable for the laboratory evaluation of therapy in canine IBD.[50] Other acute-phase proteins were less specific than CRP. One important caveat that should be emphasized is that altered CRP is not *prima facie* evidence of GI inflammation. Concurrent infections or other inflammatory conditions could cause an acute-phase response, including CRP, in affected patients.

223.5.1.10 Treatment

223.5.1.10.1 Dietary therapy

The precise immunologic mechanisms of canine and feline IBD have not yet been determined, but a prevailing hypothesis for the development of IBD is the loss of immunologic tolerance to the normal bacterial flora or food antigens. Accordingly, dietary modification may prove useful in the management of canine and feline IBD.[176,177] Several nutritional strategies have been proposed including novel proteins, hydrolyzed diets, antioxidant diets, medium chain triglyceride supplementation, low-fat diets, modifications in the omega-6 (ω-6) and omega-3 (ω-3) fatty acid ratio, and fiber supplementation. Of these strategies, some evidence-based medicine has emerged for the use of novel protein, hydrolyzed, and fiber-supplemented diets.

Food sensitivity reactions were suspected or documented in 49% of cats presented because of gastroenterologic problems (with or without concurrent dermatologic problems) in a prospective study of adverse food reactions in cats.[178] Beef, wheat, and corn gluten were the primary ingredients responsible for food sensitivity reactions in that study, and most of the cats responded to the feeding of a chicken-or

venison-based selected protein diet for a minimum of 4 weeks. The authors concluded that adverse reactions to dietary staples are common in cats with chronic GI problems and that they can be successfully managed by feeding selected protein diets. Further support for this concept comes from studies in which gastroenterologic[179–181] or dermatologic[182] clinical signs were significantly improved by the feeding of novel proteins.

Evidence is accruing that hydrolyzed diets may be useful in the nutritional management of canine IBD. The conceptual basis of the hydrolyzed diet is that oligopeptides are of insufficient size and structure to induce antigen recognition or presentation.[183,184] In one preliminary study, dogs with IBD showed significant improvement after the feeding of a hydrolyzed diet, although they had failed to respond to the feeding of a novel protein.[183] Clinical improvement could not be solely attributed to the hydrolyzed nature of the protein source because the test diet had other modified features (i.e., high digestibility, cornstarch rather than intact grains, medium-chain triglycerides, an altered ratio of ω-6 to ω-3 polyunsaturated fatty acids). Additional studies will be required to ascertain the efficacy of this nutritional strategy in the management of IBD.

Fiber-supplemented diets may be useful in the management of irritable bowel syndrome (IBS) in the dog. IBS is a poorly defined syndrome in the dog that may or may not bear resemblance to IBS in humans. Canine IBS has been defined as a chronic large bowel-type diarrhea without known cause and without evidence of colonic inflammation on colonoscopy or biopsy.[185] Dogs fulfilling these criteria were successfully managed with soluble fiber (psyllium hydrophilic mucilloid) supplementation of a highly digestible diet.[185]

1395

1396

223.5.1.10.2 Exercise

Experimental IBD in the dog is accompanied by significant abnormalities in the normal colonic motility patterns. Physical exercise has been shown to disrupt the colonic MMCs and to increase the total duration of contractions that are organized as nonmigrating motor complexes during the fed state.[186] Exercise also induces GMCs, defecation, and mass movement in both the fasted and fed states. The increased motor activity of the colon and extra GMCs that result from physical exercise may aid in normal colonic motor function.[186]

223.5.1.10.3 Pharmacologic therapy

Animals with mild to moderate forms of large bowel IBD generally respond favorably to dietary modification alone, but pharmacologic therapy will be required with more severe forms of large bowel IBD. Medical therapy includes *anti-inflammatory* (sulfasalazine and other 5-aminosalicylates, metronidazole, prednisone, budesonide), *immunosuppressive* (azathioprine, cyclosporine, chlorambucil), and *motility-modifying* (loperamide) drugs (Table 223-6).

223.5.1.10.4 Sulfasalazine

Sulfasalazine is a highly effective prostaglandin synthetase inhibitor that has proven efficacy in the therapy of large bowel IBD in the dog. Sulfasalazine is a compound molecule of 5-aminosalicylate (meselamine) and sulfapyridine linked in an azochemical bond. After oral dosing, most of the sulfasalazine is transported to the distal GI tract where cecal and colonic bacteria metabolize the drug to

its component parts. Sulfapyridine is largely absorbed by the colonic mucosa but much of the 5-aminosalicylate remains in the colonic lumen where it inhibits mucosal cyclooxygenase and the inflammatory cascade. Sulfasalazine has been recommended for the treatment of canine large bowel IBD at doses of 10 to 25 mg/kg orally, three times a day for 4 to 6 weeks. With resolution of clinical signs, sulfasalazine doses are gradually decreased by 25% at 2-week intervals and eventually discontinued while maintaining dietary management.[187] Salicylates are readily absorbed[188] and induce toxicity in cats; therefore this drug classification should be used with great caution in cats. If used in cats, some authors have recommended using half of the recommended dog dose (i.e., 5 to 12.5 mg/kg orally, three times a day).[187] Sulfasalazine use has been associated with the development of keratoconjunctivitis sicca in the dog,[189,190] so tear production should be assessed subjectively (by the pet owner) and objectively (by the veterinarian) during use.

223.5.1.10.5 Other 5-aminosalicylates

This drug classification was developed to reduce the toxicity of the sulfapyridine portion of the parent molecule (sulfasalazine) and to enhance the efficacy of the 5-aminosalicylate portion. Meselamine (Dipentum, Asachol) and dimeselamine (olsalazine) are available for use in the treatment of canine large bowel IBD. Olsalazine has been used at a dose of 5 to 10 mg/kg orally, three times a day in the dog. Despite the formulation of sulfa-free 5-aminosalicylate preparations, instances of keratoconjunctivitis sicca have still been reported in the dog.[189,190]

223.5.1.10.6 Metronidazole

Metronidazole (10 to 20 mg/kg orally, twice a day to three times a day) has been used in the treatment of mild to moderate cases of large bowel IBD in both dogs and cats. Metronidazole has been used either as a single agent or in conjunction with 5-aminosalicylates or glucocorticoids. Metronidazole is believed to have several beneficial properties, including antibacterial, antiprotozoal, and immunomodulatory effects.[191] Side effects include anorexia, hypersalivation, and vomiting at recommended doses and neurotoxicity (ataxia, nystagmus, head title, and seizures) at higher doses.[192] Side effects usually resolve with discontinuation of therapy, but diazepam may accelerate recovery of individual patients.[193]

223.5.1.10.7 Glucocorticoids

Anti-inflammatory doses of prednisone or prednisolone (1 to 2 mg/kg orally, once a day) may be used to treat IBD in dogs that have failed to respond to dietary management, sulfasalazine, or metronidazole, and as adjunctive therapy to dietary modification in feline IBD. Prednisone or prednisolone are used most frequently, because both have short durations of action, are cost-effective, and are widely available. Equipotent doses of dexamethasone are equally effective but may have more deleterious effects on brush border enzyme activity. Prednisone should be used for 2 to 4 weeks depending upon the severity of the clinical signs. Higher doses of prednisone (e.g., 2 to 4 mg/kg orally, once a day) may be needed to control severe forms of eosinophilic colitis or hypereosinophilic syndrome in cats.

Combination therapy with sulfasalazine, metronidazole, or azathioprine may reduce the overall dose of prednisone needed to achieve remission of clinical signs. As with sulfasalazine, the dose of glucocorticoid may be reduced by 25% at 1-to 2-week intervals while (it is hoped) maintaining remission with dietary modification.

Because of steroid side effects and suppression of the hypothalamic-pituitary-adrenal axis, several alternative glucocorticoids have been developed that have excellent topical (i.e., mucosal) anti-inflammatory activity but are significantly metabolized during first pass hepatic metabolism. Budesonide has been used for many years as an inhaled medication for asthma, and an enteric-coated form of the drug is now available for treatment of IBD in humans (and animals). Little clinical evidence supports of the use of this medication in canine or feline IBD, but doses of 1 mg/cat or 1 mg/dog per day have been used with some success in anecdotal cases.

223.5.1.10.8 Azathioprine

Azathioprine is a purine analog that, after DNA incorporation, inhibits lymphocyte activation and proliferation. It is rarely effective as a single agent and should instead be used as adjunctive therapy with glucocorticoids. Azathioprine may have a significant steroid-sparing effect in IBD. Doses of 2 mg/kg orally, every 24 hours in dogs and 0.3 mg/kg orally every 48 hours in cats have been used with some success in IBD. It may take several weeks or months of therapy for azathioprine to become maximally effective. Cats particularly should be monitored for side effects, including myelosuppression, hepatic disease, and acute pancreatic necrosis.

223.5.1.10.9 Cyclosporine

Cyclosporine has been used in the renal transplantation patient for its inhibitory effect on T cell function. In more recent times, cyclosporine has been used in a number of immune-mediated disorders, including keratoconjunctivitis sicca, perianal fistula (anal furunculosis), and IMHA. Evidence-based medicine studies will be needed to establish efficacy, but anecdotal experience would suggest that cyclosporine (3 to 7 mg/kg orally, twice a day) may be useful in some of the more difficult or refractory cases of IBD.

223.5.1.10.10 Chlorambucil

Chlorambucil (2 mg/m^2 orally, every other day) has been used in place of azathioprine in some difficult or refractory cases of feline IBD.

223.5.1.10.11 Motility-modifying drugs

The mixed μ,δ-opioid agonist, loperamide, stimulates colonic fluid and electrolyte absorption while inhibiting colonic propulsive motility.[194–197] Loperamide (0.08 mg/kg orally, three times a day to four times a day) may be beneficial in the treatment of difficult or refractory cases of large bowel-type IBD.

223.5.1.10.12 Probiotic therapy

Probiotics (see Table 223-6) are living organisms with low or no pathogenicity that exert beneficial effects (e.g., stimulation of innate and acquired immunity) on the health of the host. The gram-positive commensal lactic acid bacteria (e.g., *Lactobacilli*) have many beneficial health effects, including enhanced lymphocyte proliferation, innate and acquired immunity, and anti-inflammatory cytokine production. *Lactobacillus rhamnosus* GG, a bacterium used in the production of yogurt, is effective in preventing and treating diarrhea, recurrent *Clostridia difficile* infection, primary rotavirus infection, and

1396
1397
1397

atopic dermatitis in humans.[198] *Lactobacillus rhamnosus* GG and *Lactobacillus acidophilus* (strain DSM13241) have been safely colonized in the canine GI tract, although probiotic effects in the canine intestine have not been firmly established.[199a,199b] The probiotic organism, *Enterococcus faecium* (SF68), has been safely colonized in the canine GI tract, and it has been shown to increase fecal IgA content and circulating mature B (CD21+/MHC class II+) cells in young puppies. It has been suggested that this probiotic may be useful in the prevention or treatment of canine GI disease.[200] This organism may, however, enhance *Campylobacter jejuni* adhesion and colonization of the dog intestine, perhaps conferring carrier status on colonized dogs.[201]

Table • 223-6 Drug Index—Large Bowel Diarrhea

DRUG CLASSIFICATION AND EXAMPLES	DOSE	INDICATION
Anthelmintic Drugs		
Albendazole	25 mg/kg PO SID × 2 days	*Giardia* infection
Febantel	10 mg/kg PO SID × 3 days—adult dogs	*Trichuris* infection
	15 mg/kg PO SID × 3 days—puppies	*Trichuris* infection
Fenbendazole	50 mg/kg PO SID × 3 days	*Trichuris, Ancylostoma, Giardia* infection
Ivermectin	200 µg/kg SQ once	Larvicidal for *T. canis*
Mebendazole	22 mg/kg PO SID × 3 days	*Trichuris* infection
Metronidazole	25 mg/kg PO BID × 5 days	*Giardia* infection
Milbemycin oxime	0.5 mg/kg PO once per month	*Trichuris* preventive
Praziquantel	44 mg/kg PO once	*Heterobilharzia*
Pyrantel pamoate	5 mg/kg PO dog, 20 mg/kg cat	*Ancylostoma, Toxocara*
Antibiotics		
Ampicillin	22 mg/kg PO IV TID	*Salmonella, E. coli, Clostridium perfringens*
Cefadroxil	22 mg/kg PO BID	*Salmonella, E. coli*
Chloramphenicol	44 mg/kg PO TID—dogs	*Campylobacter*
	11 mg/kg PO BID—cats	*Campylobacter*
Enrofloxacin	5 mg/kg PO IM SQ BID	*Salmonella, E. coli*
Erythromycin	15–20 mg/kg PO TID	*Campylobacter, C. perfringens*
Metronidazole	10–20 mg/kg PO BID-TID	*C. perfringens*
Orbifloxacin	2.5–7.5 mg/kg PO SID	*Salmonella, E. coli*
Trimethoprim sulfonamide	30 mg/kg PO IM SQ BID	*Salmonella*
Tylosin	40–80 mg/kg PO SID	IBD, *C. perfringens*
Antifungal Drugs		
Amphotericin B	2–3 mg/kg IV QOD administered to a cumulative dose of 24–27 mg/kg	Histoplasmosis, pythiosis, protothecosis
Itraconazole	5 mg/kg PO BID for several months	Histoplasmosis, pythiosis, protothecosis
Ketoconazole	10–15 mg/kg PO BID several months	Histoplasmosis, pythiosis, protothecosis
Anti-Inflammatory Drugs		
Budesonide	1 mg/cat or 1 mg/dog PO SID	IBD
Meselamine	10 mg/kg PO TID	IBD
Metronidazole	10–20 mg/kg PO BID-TID for 4–6 weeks	IBD
Olsalazine	5–10 mg/kg PO TID for 4–6 weeks	IBD
Prednisolone	4.0–6.0 mg/kg PO SID for 4–6 weeks	Feline eosinophilic colitis
Prednisone	1.0–2.0 mg/kg PO SID for 4–6 weeks	IBD
Sulfasalazine	10–25 mg/kg PO TID for 4–6 weeks—dogs	IBD, ulcerative colitis
	5–12.5 mg/kg PO TID for 2–4 weeks—cats	Refractory IBD
Immunosuppressive Drugs		
Azathioprine	2 mg/kg PO SID for 4–6 weeks—dogs	IBD
Chlorambucil	2 mg/m^2 PO every other day for 4–6 weeks	IBD
Cyclosporine	3–7 mg/kg PO BID for 4–6 weeks	IBD
Motility-Modifying Drugs		
Loperamide	0.08 mg/kg PO TID-QID	IBD, IBS
Propantheline	0.25 mg/kg PO BID-TID	IBS
Aminopentamide	0.01–0.03 mg/kg PO BID-TID	IBS
Probiotics		
Enterococcus faecium (SF68)	5 × 10^8 colony-forming units/day	IBD

Lactobacillus rhamnosus GG	1×10^9 to 5×10^{11} colony-forming units/day	IBD

PO, per os; SID, once per day; IV, intravenous; TID, three times per day; BID, twice per day; QOD, every other day.

Two recent studies have shown that many commercial veterinary probiotic preparations are not accurately represented by label claims. Quality control appears to be deficient for many of these formulations.[202,203] Until these products are more tightly regulated, veterinarians should probably view product claims with some skepticism.

223.5.1.10.13 Behavioral modification

IBD and IBS very likely have underlying behavioral components. Abnormal personality traits and potential environmental stress factors were identified in 38% of dogs in one study.[185] Multiple factors were present in affected households, including travel, relocation, house construction, separation anxiety, submissive urination, noise sensitivity, and aggression.[185] The role of behavior in the pathogenesis and therapy of canine and feline GI disorders remains largely unexplored.

223.5.1.11 Prognosis

Most reports indicate that the short-term prognosis for control of IBD is good to excellent. After completion of drug therapy, many animals are able to maintain remission of signs with dietary management alone. Treatment failures are uncommon and are usually due to (1) incorrect diagnosis (it is especially important to rule out alimentary lymphosarcoma), (2) presence of severe disease such as histiocytic ulcerative colitis and PLE or irreversible mucosa lesions such as fibrosis, (3) poor client compliance with appropriate drug and dietary recommendations, (4) use of inappropriate drugs or nutritional therapy, and (5) presence of concurrent disease such as small intestinal bacterial overgrowth or hepatobiliary disease.[187] The prognosis for cure of IBD is poor, and relapses should be anticipated.

223.5.2 Histiocytic Ulcerative Colitis

223.5.2.1 Cause

Histiocytic ulcerative colitis is a rare disorder of the dog that has been reported sporadically since 1965.[204–209] Most cases have been reported in the boxer breed, although recent reports have included the French bulldog, mastiff, Alaskan Malamute, and Doberman pinscher breeds. The disease typically affects the young boxer, with the majority (78%) developing clinical signs before 2 years of age. Males and females appear to be equally affected. The pathogenesis of this disorder is incompletely understood, but a bacterial pathogenesis has recently been proposed.[209a] As with Whipple's disease in humans and Johne's disease in cattle, the presence of periodic acid-Schiff (PAS)-positive macrophages and intralesional bacteria have suggested a number of infectious agents such as mycobacteria, rickettsiae, chlamydiae, and mycoplasmae.[208] Vascular abnormalities of the colonic mucosa and intrinsic abnormalities of the PAS^+ histiocytes have also been implicated in the pathogenesis of this syndrome.

223.5.2.2 Pathophysiology

Histiocytic ulcerative colitis lesions are characterized by increased numbers of IgG+, IgG3+, and IgG4+ plasma cells, CD3+ T cells, MHC class II+ cells, L1+ cells, and PAS+ cells in the lamina propria, and decreased goblet cell numbers in the epithelium (see Figure 223-8).[208] Canine histiocytic ulcerative colitis appears to be more typical of a Th2-type response (similar to human ulcerative colitis), whereas canine large intestinal IBD appears to be more of a Th1-type response.[160]

223.5.2.3 Clinical Examination

Affected animals have classic signs of large bowel disease (e.g., mucoid bloody diarrhea, frequent episodes of urgency and straining to defecate). As the disease progresses, continuing intestinal blood and protein loss causes some animals to lose significant amounts of body weight. The most remarkable findings on physical examination are pain during digital palpation of the anorectum and thickened rectal mucosa along with blood pigments. Moderate to severe cachexia may be a clinical feature of more chronically affected animals.

223.5.2.4 Diagnosis

Colonoscopy and biopsy are the diagnostic methods of choice.[206] Endoscopic findings are variable and include diffusely hyperemic and irregular colonic mucosa with multifocal, petechial hemorrhages; nodular and corrugated mucosa; edema and fibrosis; and, multifocal, scattered ulcers throughout the mucosa.[206,207] Histopathologically, a marked expansion of the lamina propria occurs with a diffuse infiltration of PAS-positive histiocytes. Histiocytic infiltration is often accompanied by multifocal, superficial mucosal ulcers with neutrophil, lymphocyte, and plasma cell infiltration.

223.5.2.5 Treatment.

Sulfasalazine has been the drug of choice for this disorder, and affected animals showed some initial clinical improvement only to experience relapses during the course of the disease. The disease was thought to be progressive and requiring lifelong therapy. More recently, therapeutic cures have been reported with enrofloxacin therapy, again implying an underlying bacterial pathogenesis.[209a]

223.5.2.6 Prognosis

If histiocytic ulcerative colitis is at an advanced stage at the time of diagnosis, treatment often does not improve clinical signs and a poor prognosis is warranted.

223.5.3 Typhlitis

223.5.3.1 Cause

Primary inflammation or infection of the cecum is a rare clinical problem in the dog and cat. Typhlitis more often develops secondarily as part of a typhlocolitis or ileotyphlocolitis syndrome.[210] Eosinophilic typhlitis, for example, has been reported in association with eosinophilic coloproctitis and ileitis in one dog,[210] and

neutrophilic typhlocolitis was observed in a group of gnotobiotic dogs experimentally infected with *Campylobacter* spp.[124] Typhlitis usually responds to the same medical therapies that are used to treat ileocolitis. In rare cases, surgical resection may be required due to obstruction and abscessation.[211]

223.5.3.2 Pathophysiology

The cecum responds pathophysiologically in much the same way that the colon responds to inflammation, except that size and orientation predispose the cecum to obstruction, abscessation, and rupture.

223.5.3.3 Clinical Examination

Dogs affected with typhlocolitis may have mild discomfort on abdominal palpation, or there may be severe abdominal pain with cecal obstruction and abscessation.

223.5.3.4 Diagnosis

Abdominal ultrasonography may be useful in documenting thickening of the cecal mucosa in some cases of typhlocolitis, but definitive diagnosis usually requires direct endoscopic examination. Ultrasonography is more useful in the diagnosis of obstructive lesions of the cecum (e.g., abscessation, neoplasia). Survey radiography is not that useful unless sequelae to infection are noted (e.g., abscessation, inversion, rupture). 1398

1399

223.5.3.5 Treatment

Infectious typhlitis is best treated with antimicrobial and other therapy as outlined for treatment of inflammatory and infectious colitis.

223.5.3.6 Prognosis

The prognosis for typhlocolitis lesions is generally favorable, particularly if they are diagnosed prior to the onset of smooth muscle hypertrophy and obstruction.

223.5.4 Colitis Associated with Perianal Fistula

Perianal fistula or anal furunculosis is a chronic and painful perianal disease of dogs, characterized by inflammation, ulceration, and sinus tracts involving the tissues surrounding the anus.[212,213] Clinical signs include tenesmus, hematochezia, and an ulcerated malodorous perianal region, resulting in pain, anorexia, and weight loss. Inflammation and sinus tracts may involve the rectum and descending colon in some animals, and it may be difficult, if not impossible, to attribute clinical signs to the colitis or the perianal fistula. Because of the high incidence of colitis in dogs affected with perianal fistula, it has been suggested that colonic biopsies should be obtained in all animals affected with perianal fistula.[213] It has also been suggested that affected animals should be managed with a novel protein diet as part of the overall medical therapy.[212] A more detailed discussion of perianal fistula may be found in Chapter 224.

223.6 OBSTRUCTION

223.6.1 Neoplasia

223.6.1.1 Cause

In dogs, tumors of the large intestine are more common than tumors of the stomach and small intestine. The mean age of dogs affected with colonic neoplasia is variably reported between 7 and 11 years of age.[214] Most colonic tumors of dogs are malignant and include the adenocarcinomas, lymphosarcomas, and GI stromal tumors (leiomyosarcoma, neurofibrosarcoma, fibrosarcoma, and ganglioneuroma).[215–224] Leiomyosarcomas are the most common (91%) of the GI stromal tumors.[217–220] Most colonic neoplasia develop in the descending colon and rectum, although leiomyosarcomas more frequently develop in the cecum.[217,219] Local tumor invasion apparently occurs at a slower rate with canine colonic neoplasia, and metastasis to distant sites is relatively uncommon. Benign colonic neoplasia (e.g., adenomas, adenomatous polyps, leiomyomas) also occur, although they are less common than malignant tumors. Malignant transformation of adenomatous polyps to carcinoma *in situ* and invasive adenocarcinoma has been demonstrated in the dog just as it has in humans.[214,225,226,226b] Extramedullary plasmacytomas are an uncommon tumor of the GI tract but occur in the large intestine and rectum.[227,228] All of the aforementioned tumors are associated with signs of inflammation and obstruction (i.e., hematochezia, tenesmus, dyschezia). Carcinoids (rare 5-hydroxytryptamine [5-HT]-secreting tumors) are occasionally associated with diarrhea because of the effects of 5-HT on secretion and motility.

In cats, adenocarcinoma (46%) is the most common tumor of the large intestine, followed by lymphosarcoma (41%) and mast cell tumors (9%).[229–231] The mean age of cats affected with colonic neoplasia is 12.5 years. The descending colon (39%) and the ileocolic sphincter (28%) are the most common sites of colonic neoplasia in the cat. Unlike colonic tumors in the dog, feline colonic tumors have a high rate (63%) of metastasis and, of course, metastasis is associated with decreased survival time. Metastatic sites include colonic lymph nodes, mesenteric lymph nodes, liver, spleen, bladder, urethra, omentum, mesocolon, lungs, duodenum, and peritoneum.

223.6.1.2 Pathophysiology

Mechanical obstruction is the most common pathophysiologic consequence of locally invasive colonic tumors. Other non-neoplastic processes such as intussusception, FIP granuloma, fibrosing stricture, linear and nonlinear foreign bodies, hematoma, and phycomycosis lesions also cause intraluminal obstruction. Prolonged obstruction induces smooth muscle hypertrophy proximal to the site of the obstruction.[232] Other pathophysiologic consequences of intestinal obstruction are pronounced fluid secretion and malabsorption of water and solutes; fluid, electrolyte, and acid-base disturbances; proliferation and translocation of luminal bacteria; and inflammation, devitalization, and perhaps even perforation of the colon. Secretory diarrheas have been reported with carcinoids of the rectum, colon, and intestine.

223.6.1.3 Clinical Examination

Most affected dogs have signs of hematochezia, mucoid feces, tenesmus, and dyschezia of varying severity. Importantly, the clinical signs observed with colorectal neoplasia are often indistinguishable from other causes of obstruction or chronic colitis. Hematochezia is infrequently reported with leiomyosarcomas or leiomyomas, presumably because these tumors do not typically involve the mucosa. Other clinical signs depend on the tumor type and location. Vomiting, malabsorption, and cachexia may be observed, for example, when multifocal or diffuse tumors (e.g., lymphosarcoma) involve the proximal portions of the GI tract. GI stromal tumors, particularly the leiomyomas, have been associated with hypoglycemia and the resulting clinical signs of muscular weakness and seizure activity.[233] Functional plasmacytomas secrete a single class of immunoglobulin and affected animals may go on to develop hyperviscosity syndrome (e.g., retinal bleeding, epistaxis). If colonic perforation has occurred, animals may be presented moribund with fever, lethargy, anorexia, vomiting, abdominal pain, and collapse.

Vomiting (65%), diarrhea (52%), and weight loss (46%) are common clinical signs in cats with colonic neoplasia.[229] Most cats with colonic (and alimentary) lymphosarcoma are FeLV-negative. These lymphomas are thought to be caused by FeLV, with integrated virus causing neoplastic transformation in the absence of viral replication. Although most lymphomas in cats appear to be comprised of malignant T lymphocytes, most colonic (and alimentary) lymphomas are of B cell origin. Alimentary and colonic lymphomas originate primarily from submucosal lymphocytes, mucosal lymphoid follicles, or both, although one recent study reported an epitheliotropic form of T cell intestinal lymphomas.[234] Epitheliotropic T cell lymphomas have not yet been reported in the feline colon.

223.6.1.4 Diagnosis

Canine rectal adenocarcinomas are palpable in 60% to 80% of clinical cases, but colonic and cecal lesions are not as readily apparent on physical examination.[214,226,232,235,236] More than 50% of cats with colonic masses have a palpable abdominal mass.[229]

Survey and contrast radiographic and ultrasonographic studies have been used with varying levels of success in the diagnosis of canine and feline colonic neoplasia. Annular stenotic lesions associated with adenocarcinoma of the colon may manifest as proximal colonic dilation on survey radiographs.

Radiographic contrast material more precisely outlines the narrowing of the lumen at the site of the tumor. Although still of some clinical utility, contrast studies have been largely superceded by ultrasonography and other imaging modalities. Ultrasonography is presently considered to be the most effective means of diagnosing colonic tumors in dogs and cats and appears to be useful in evaluating mural lesions and associated abdominal changes such as lymphadenopathy.[236] Ultrasonography was reported to be useful 84% of the time in localizing feline colonic neoplasia in one study.[229] Ultrasonographic features of colonic tumors include transmural wall thickening with complete loss of the normal wall layering, fluid accumulation proximal to the lesion, and reduced regional motility.[236] Transabdominal fine needle aspiration, peritoneal fluid cytology, and endoscopic exfoliative cytology may be useful in the diagnosis of lymphoma, but histopathology is generally required for a definitive diagnosis of other colonic neoplasia. CT and magnetic resonance imaging (MRI) scanning have not been sufficiently evaluated at this time for reasonable comparisons to be made with ultrasonography.

1399 1400

Flexible colonoscopy with mucosal biopsy is the preferred method of diagnosis for colonic neoplasia. Endoscopic abnormalities may include mass effect, mucosal bleeding, increased mucosal friability, erosions and ulcers, and circumferential luminal narrowing with submucosal infiltrative lesions. Multiple biopsy specimens should always be taken from diseased tissue, adjacent healthy tissue, and the transition zone between healthy and diseased tissue. With tumor necrosis, the pathologist will have a much better chance of diagnosing and staging the disease by evaluating non-necrotic tissue.

223.6.1.5 Treatment

The treatment of colonic neoplasia will depend upon tumor type, anatomic location, and presence and extent of metastases. Complete surgical excision is the recommended therapy for focal adenocarcinomas, cecal leiomyosarcomas, and obstructive lymphomas. Multiagent chemotherapy (prednisone, vincristine, cyclophosphamide) has been used to treat colonic lymphoma, but it does not appear to alter survival time in affected cats.[229] Cyclo-oxygenase II (COX II) up-regulation may contribute to the growth characteristics of some canine colonic neoplasia.[237–239] Selective COX II inhibitors (e.g., piroxicam, meloxicam) may therefore be useful in the treatment of some canine colonic neoplasia. Plasmacytomas may be managed with adjuvant chemotherapy (e.g., prednisone, melphalan) after surgical excision. Radiation therapy has been used to palliate recurrent adenocarcinomas with varying results and complications; however, postradiation peritonitis and perforation have been reported in some cases.[240]

223.6.1.6 Prognosis

The prognosis for adenomatous polyps, leiomyomas, and fibromas is generally favorable. Adenocarcinomas, lymphosarcomas, and plasmacytomas tend to recur, metastasize, or both to distant sites. Dogs with annular colorectal adenocarcinomas have a particularly poor prognosis with a median survival time (MST) of only 1.6 months.[214,235] The prognosis for most malignant tumors is generally guarded. Surgical resection alone results in 22 month (dogs) and 15 month (cats) average survival times in dogs and cats.[214,229] It should be noted that cats undergoing subtotal colectomy for colonic adenocarcinoma had a longer survival time than those receiving mass resection only (MST of 138 days versus 68 days).[229] Not surprisingly, cats with metastatic lesions had much shorter survival times, 49 days versus 259 days.[229]

223.6.2 Intussusception

223.6.2.1 Cause

Intussusception is an invagination of one segment of the GI tract into the lumen of an adjoining segment. The *intussusceptum* is the invaginated segment of the alimentary tract, whereas the *intussuscipiens* is the enveloping segment. Invagination may occur in an antegrade (aborad) or retrograde (orad) direction, but is most commonly in the antegrade direction. Any portion of the alimentary tract may be involved, but enterocolic intussusceptions account for almost two thirds of the published cases in dogs and cats. Enterocolic intussusceptions can be further divided into three types: (1) cecocolic (or cecal inversion), with the inverted cecum forming the apex[241]; (2) ileocolic, with the ileum forming the apex; and (3) ileocecal, with the ileum forming the apex.[242] Of these three forms of enterocolic intussusception, the ileocolic intussusception is the one most frequently encountered in clinical practice. A number of conditions are

reported to predispose to intussusception, including intestinal parasitism, viral enteritis, foreign bodies, and masses, but in dogs and cats most intussusceptions are idiopathic.[243–245]

223.6.2.2 Pathophysiology

The initiating events in an intussusception are often difficult to identify retrospectively, but all intussusceptions appear to share three important features: (1) inhomogeneity in a bowel segment—a region in which the GI tract undergoes a sudden anatomic change in diameter (e.g., ileocolic junction) or a bowel segment that is either flaccid or indurated; (2) mechanical linkage of nonadjacent segments—which can be intraluminal (e.g., linear foreign bodies, parasites) or extramural (e.g., fibrous adhesions or bands); and (3) peristaltic activity of the gut.[242]

Invagination begins as a result of peristaltic contraction. Once the invagination has begun, its progress may be rapid, involving as much as several centimeters of intestinal tract within just a few hours. Invagination and intussusception result in luminal obstruction, which may be partial or complete. Obstruction usually results in distension of the bowel segment proximal to the intussusception. The degree of distension is dependent upon the completeness and duration of the obstruction, volume of fluid secretion, degree of vascular compromise, and volume of gas production from bacterial fermentation. Because the mesentery and blood supply are included in the invaginating segment, vascular compromise can occur, which initially leads to intramural hemorrhage and edema and eventually to ischemia and necrosis of the bowel. Full-thickness necrosis may ensue, but perforations are rare.

223.6.2.3 Clinical Examination

The most important clinical signs with ileocolic intussusceptions are intermittent vomiting, progressive loss of appetite, mucoid bloody diarrhea, and a palpable cylinder-shaped mass in the cranial abdomen. Abdominal pain is not a consistent finding in affected animals. Clinical signs may persist for several weeks, and affected animals eventually succumb to the effects of starvation rather than dehydration, electrolyte imbalances, or acid-base disturbances.

223.6.2.4 Diagnosis

With some ileocolic intussusceptions, the intussuscepted bowel may protrude through the anus and must be differentiated from a rectal prolapse. This is accomplished by passing a blunt probe between the protruding segment and the anal sphincter. If the probe can be passed cranial to the pubis without reaching a fornix, then the protruding bowel is the apex of an intussusception rather than rectal prolapse.

Survey abdominal radiographic findings may be suspicious for intussusception (Figure 223-10, *A*). Barium contrast studies (barium enema or upper GI series) are often diagnostic, but abdominal ultrasonography is the preferred method of diagnosis. The appearance of a targetlike mass (consisting of two or more hyperechoic and hypoechoic concentric rings in transverse section) or the appearance of multiple hyperechoic and hypoechoic parallel lines in longitudinal section is virtually diagnostic of an intussusception (Figure 223-10, *B*).[246] The ultrasound scan might also identify a mass associated with the intussusception. Endoscopy may be performed in suspected cases of suspected neoplasia, otherwise endoscopy does not confer any additional benefits over abdominal ultrasound or CT scanning.

223.6.2.5 Treatment

The surgical management of ileocolic intussusception involves either reduction or resection, and anastomosis, or both.[247,248] Secretory diarrhea may persist after relief of the obstruction, and affected animals may need continuous crystalloid and colloidal therapy. If possible, the ileocecal sphincter should be preserved to reduce reflux and contamination of the distal small bowel. Cecocolic intussusceptions or inversions should also be treated with surgical resection. Surgical resection of the cecocolic intussusceptions is generally curative. Enteroplication procedures have been recommended,[249] but they do not appear to reduce recurrence rates.[247,248]

1400
1401

223.6.2.6 Prognosis

The most common complications after treatment of intussusception are recurrence, dehiscence of the anastomosis, ileus, intestinal obstruction, peritonitis, and short bowel syndrome. The recurrence rate in dogs is reported to be between 11% and 20%. In dogs in which no surgical procedure was performed to prevent recurrence, intussusception recurred in 25% of dogs that underwent manual reduction alone and in 19% of dogs that underwent resection and anastomosis. Enteroplication does not appear to reduce recurrence rates any further.[247,248] Indeed, 19% of dogs undergoing enteroplication in one study experienced severe complications that required a second surgery. Intestinal obstruction was a complication of the enteroplication in those patients.[248]

223.7 HYPOMOTILITY AND DYSMOTILITY

223.7.1 Constipation

223.7.1.1 Cause

The etiopathogenesis of idiopathic megacolon is still incompletely understood. Several reviews have emphasized the importance of considering an extensive list of differential diagnoses (e.g., neuromuscular, mechanical, inflammatory, metabolic and endocrine, pharmacologic, environmental, and behavioral causes) for the obstipated cat (Box 223-1; reviewed in reference 250). A review of published cases suggests that 96% of cases of obstipation are accounted for by idiopathic megacolon (62%), pelvic canal stenosis (23%), nerve injury (6%), or Manx sacral spinal cord deformity (5%).[52] A smaller number of cases are accounted for by complications of colopexy (1%) and colonic neoplasia (1%); colonic hypo-or aganglionosis was suspected, but not proved, in another 2% of cases. Inflammatory, pharmacologic, and environmental and behavioral causes were not cited as predisposing factors in any of the original case reports. Endocrine factors (e.g., obesity, hypothyroidism) were cited in several cases, but were not necessarily impugned as part of the pathogenesis of megacolon. It is important to consider an extensive list of differential diagnoses in an individual animal, but it should be kept in mind that most cases are idiopathic, orthopedic, or neurologic in origin. Behavioral (e.g., stress) or environmental (e.g., competition for the litter box) factors, or both, may play an important role in the development of this lesion, but they have not been very well characterized in retrospective or prospective studies.

223.7.1.2 Pathophysiology

Megacolon develops through two pathologic mechanisms: (1) *dilation* and (2) *hypertrophy. Dilated megacolon* is the end stage of colonic dysfunction in idiopathic cases. Cats affected with idiopathic dilated megacolon have permanent loss of colonic structure and function. Medical therapy may be attempted in such cases, but most affected cats eventually require colectomy. *Hypertrophic megacolon*, on the other hand, develops as a consequence of obstructive lesions (e.g., malunion of pelvic fractures, tumors, foreign bodies).

Hypertrophic megacolon may be reversible with early pelvic osteotomy, or it may progress to irreversible dilated megacolon if appropriate therapy is not instituted.[251]

Constipation and *obstipation* are earlier manifestations of the same problem. Constipation is defined as infrequent or difficult evacuation of feces but does not necessarily imply a permanent loss of function. Many cats suffer from one or two episodes of constipation without further progression. Intractible constipation that has become refractory to cure or control is referred to as *obstipation*. The term *obstipation* implies a permanent loss of function. A cat is assumed to be obstipated only after several consecutive treatment failures. Recurring episodes of constipation or obstipation may culminate in the syndrome of *megacolon*.

1401

1402

223.7.1.2.1 **Box • 223-1 Differential Diagnosis of Constipation in the Cat**

223.7.1.2.1.1 **Neuromuscular Dysfunction**

Colonic smooth muscle: idiopathic megacolon, aging

Spinal cord disease: lumbosacral disease, cauda equina syndrome, sacral spinal cord deformities (Manx cat)

Hypogastric or pelvic nerve disorders: traumatic injury, malignancy, dysautonomia

Submucosal or myenteric plexus neuropathy: dysautonomia, aging

223.7.1.2.1.2 **Mechanical Obstruction**

Intraluminal: foreign material (bones, plant material, hair), neoplasia, rectal diverticula, perineal hernia, anorectal strictures

Intramural: neoplasia

Extraluminal: pelvic fractures, neoplasia

223.7.1.2.1.3 **Inflammation**

Perianal fistula, proctitis, anal sac abscess, anorectal foreign bodies, perianal bite wounds

223.7.1.2.1.4 **Metabolic and Endocrine**

Metabolic: dehydration, hypokalemia, hypercalcemia

Endocrine: hypothyroidism, obesity, nutritional secondary hyperparathyroidism

223.7.1.2.1.5 **Pharmacological**

Opioid agonists, cholinergic antagonists, diuretics, barium sulfate, phenothiazines

223.7.1.2.1.6 **Environmental and Behavioral**

Soiled litter box, inactivity, hospitalization, change in environment

The pathogenesis of idiopathic dilated megacolon appears to involve functional disturbances in colonic smooth muscle. *In vitro* isometric stress measurements have been performed on colonic smooth muscle obtained from cats suffering from idiopathic dilated megacolon.[252,253] Megacolonic smooth muscle develops less isometric stress in response to neurotransmitter (acetylcholine, substance P, cholecystokinin), membrane depolarization (potassium chloride), or electrical field stimulation, when compared with healthy controls.[252,253] Differences have been observed in longitudinal and circular smooth muscle from the descending and ascending colon. No significant abnormalities of smooth muscle cells or of myenteric neurons were observed on histologic evaluation. These studies initially suggested that the disorder of feline idiopathic megacolon is a generalized dysfunction of colonic smooth muscle and that treatments aimed at stimulating colonic smooth muscle contraction might improve colonic motility. More recent studies suggest that the lesion may begin in the descending colon and progress to involve the ascending colon over time.[254]

223.7.1.3 Clinical Examination

223.7.1.3.1 History

Constipation, obstipation, and megacolon may be observed in cats of any age, sex, or breed; however, most cases are observed in middle-aged (mean: 5.8 years) male cats (70% male, 30% female) of domestic shorthair (DSH) (46%), domestic longhair (15%), or Siamese (12%) breeding.[52] Affected cats are usually presented for reduced, absent, or painful defecation for a period of time ranging from days to weeks or months. Some cats are observed making multiple, unproductive attempts to defecate in the litter box, whereas other cats may sit in the litter box for prolonged periods of time without assuming a defecation posture. Dry, hardened feces are observed inside and outside of the litter box. Occasionally, chronically constipated cats have intermittent episodes of hematochezia or diarrhea due to the mucosal irritant effect of fecal concretions. This may give the pet owner the erroneous impression that diarrhea is the primary problem. Prolonged inability to defecate may result in other systemic signs, including anorexia, lethargy, weight loss, and vomiting.

223.7.1.3.2 Physical examination

Colonic impaction is a consistent physical examination finding in affected cats. Other findings will depend upon the severity and pathogenesis of constipation. Dehydration, weight loss, debilitation, abdominal pain, and mild to moderate mesenteric lymphadenopathy may be observed in cats with severe idiopathic megacolon. Colonic impaction may be so severe in such cases as to render it difficult to differentiate impaction from colonic, mesenteric, or other abdominal neoplasia. Cats with constipation due to dysautonomia may have other signs of autonomic nervous system failure, such as urinary and fecal incontinence, regurgitation due to megaesophagus, mydriasis, decreased lacrimation, prolapse of the nictitating membrane, and bradycardia. Digital rectal examination should be carefully performed with sedation or anesthesia in all cats. Pelvic fracture malunion may be detected on rectal examination in cats with pelvic trauma. Rectal examination might also identify other unusual causes of constipation, such as foreign bodies, rectal diverticula, stricture, inflammation, or neoplasia. Chronic tenesmus may be associated with perineal herniation in some cases.[250] A complete neurologic examination, with special emphasis on caudal spinal cord function, should be performed to identify neurologic causes of constipation (e.g., spinal cord injury, pelvic nerve trauma, Manx sacral spinal cord deformity).

223.7.1.3.3

Diagnosis

Although most cases of obstipation and megacolon are unlikely to have significant changes in laboratory data (e.g., CBC, serum chemistry, urinalysis), these tests should nonetheless be performed in all cats presented for constipation. Metabolic causes of constipation, such as dehydration, hypokalemia, and hypercalcemia may be detected in some cases. Basal serum T_4 concentration and other thyroid function tests should also be considered in cats with recurrent constipation and other signs consistent with hypothyroidism. Although hypothyroidism was documented in only one case of obstipation and megacolon, obstipation is a frequent clinical sign in kittens affected with congenital or juvenile-onset hypothyroidism.[52] Constipation could also theoretically develop after successful treatment of feline hyperthyroidism.

Abdominal radiography should be performed in all constipated cats to characterize the severity of colonic impaction and to identify predisposing factors such as intraluminal radio-opaque foreign material (e.g., bone chips), intraluminal or extraluminal mass lesions, pelvic fractures, and spinal cord abnormalities (Figure 223-11). The radiographic findings of colonic impaction cannot be used to distinguish between constipation, obstipation, and megacolon in idiopathic cases. First or second episodes of constipation in some cats may be severe and generalized but may still resolve with appropriate treatment.

Ancillary studies may be indicated in some cases. Extraluminal mass lesions may be further evaluated by abdominal ultrasonography and guided biopsy, whereas intraluminal mass lesions are best evaluated by endoscopy. Colonoscopy may also be used to evaluate the colon and anorectum for suspected inflammatory lesions, strictures, sacculations, and diverticula. Barium enema contrast radiography may be used if colonoscopy is not possible. Both colonoscopy and barium enema contrast radiography will require general anesthesia and evacuation of impacted feces. Cerebrospinal fluid analysis, CT or MRI, and electrophysiologic studies should be considered in animals with evidence of neurologic impairment. Finally, colonic biopsy or anorectal manometry will be necessary to diagnose suspected cases of aganglionic megacolon.

1402 1403

Figure 223-11 Barium enema in a 12-year-old cat with idiopathic constipation and megacolon.

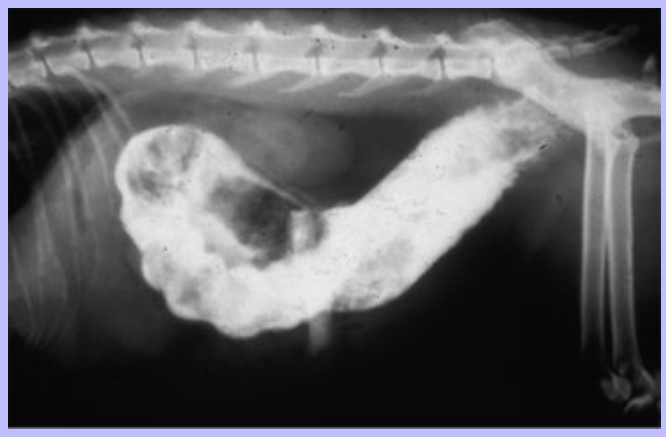

Figure 223-12 Therapeutic approach to feline constipation and megacolon.

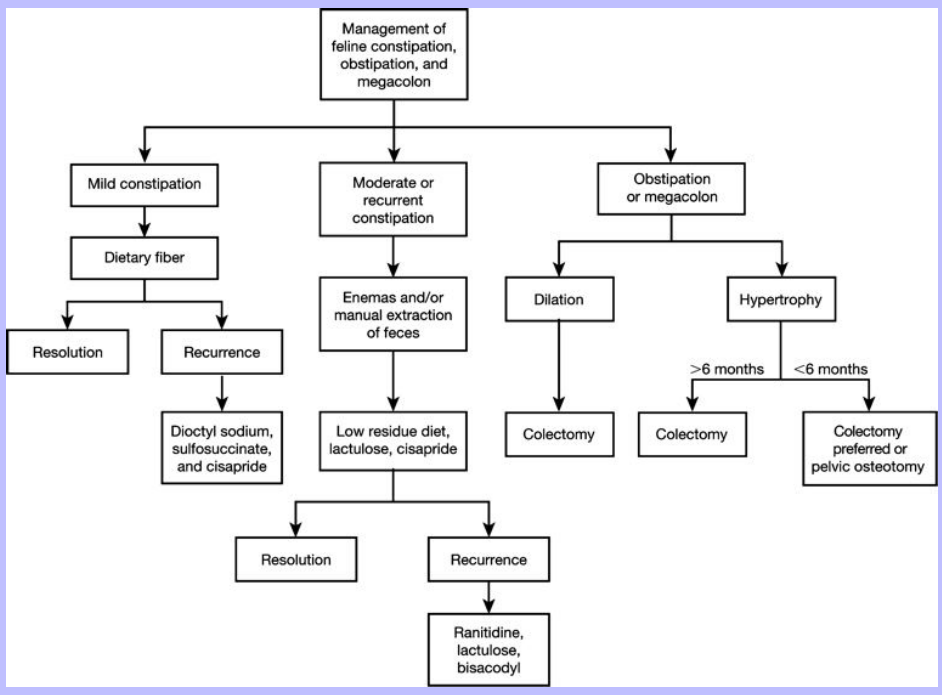

223.7.1.3.4 Treatment

The specific therapeutic plan will depend upon the severity of constipation and the underlying cause (Figure 223-12; Table 223-7).[250] Medical therapy may not be necessary with first episodes of constipation. First episodes are often transient and resolve without therapy. Mild to moderate or recurrent episodes of constipation, on the other hand, usually require some medical intervention. These cases may be managed, often on an outpatient basis, with dietary modification, water enemas, oral or suppository laxatives, colonic prokinetic agents, or a combination of these therapies. Severe cases of constipation usually require brief periods of hospitalization to correct metabolic abnormalities and to evacuate impacted feces using water enemas, manual extraction of retained feces, or both. Follow-up therapy in such cases is directed at correcting predisposing factors and preventing recurrence. Subtotal colectomy will become necessary in cats suffering from obstipation or idiopathic dilated megacolon. These cats, by definition, are unresponsive to medical therapy. Although pelvic osteotomy is described for cats with pelvic canal stenosis,[225] subtotal colectomy is an effective treatment and is considered the standard of surgical care.[280] An algorithm for the therapeutic approach to the constipated, obstipated, and megacolonic cat is outlined in Figure 223-12.

223.7.1.4 Removal of Impacted Feces

Removal of impacted feces may be accomplished through the use of rectal suppositories, enemas, or manual extraction.

223.7.1.4.1

Rectal suppositories

1403

A number of pediatric rectal suppositories are available for the management of mild constipation. These include dioctyl sodium sulfosuccinate (emollient laxative), glycerin (lubricant laxative), and bisacodyl (stimulant laxative). The use of rectal suppositories requires a compliant pet and pet owner. Suppositories can be used alone or in conjunction with oral laxative therapy.

1404

Table • 223-7 Drug Index—Constipation

DRUG CLASSIFICATION AND EXAMPLE	DOSE
Rectal Suppositories	
Dioctyl sodium sulfosuccinate (Colace, Mead Johnson)	1–2 pediatric suppositories
Glycerin	1–2 pediatric suppositories
Bisacodyl (Dulcolax; Boehringer Ingelheim)	1–2 pediatric suppositories
Enemas	
Warm tap water	5–10 mL/kg
Warm isotonic saline	5–10 mL/kg
Dioctyl sodium sulfosuccinate (Colace, Mead Johnson)	5–10 mL/cat
Dioctyl sodium sulfosuccinate (Disposaject, PittmanMoore)	250 mg (12 ml) given pre rectum
Mineral oil	5–10 mL/cat
Lactulose (Cephulac, Merrell Dow; Duphalac, Reid Rowell)	5–10 mL/cat
Oral Laxatives	
Bulk laxatives	
Psyllium (Metamucil, Searle)	1–4 tsp mixed with food, every 24 or 12 hours
Canned pumpkin	1–4 tsp mixed with food, every 24 hours
Coarse wheat bran	1–4 tblsp mixed with food, every 24 hours
Emollient laxatives	
Dioctyl sodium sulfosuccinate (Colace, Mead Johnson)	50 mg orally, every 24 hours
Dioctyl calcium sulfosuccinate (Surfax, Hoechst)	50 mg orally, every 24 or 12 hours as needed
Lubricant laxatives	
Mineral oil	10–25 ml orally, every 24 hours
Petrolatum (Laxatone, Evsco)	1–5 ml orally, every 24 hours
Hyperosmotic laxatives	
Lactulose (Cephulac, Merrell Dow; Duphalac, Reid Rowell)	0.5 ml/kg orally, every 12 to 8 hours as needed
Stimulant laxatives	
Bisacodyl (Dulcolax, Boehringer Ingelheim)	5 mg orally, every 24 hours
Prokinetic Agents	
Cisapride (compounding pharmacies)	0.1–1.0 mg/kg orally every 12 to 8 hours
Tegaserod (Zelnorm, Novartis)[257]-dogs	0.05–0.10 mg/kg orally, twice a day
Ranitidine (Zantac, Glaxo SmithKline)	1.0–2.0 mg/kg orally, every 12 to 8 hours
Nizatidine (Axid, Eli Lilly)	2.5–5.0 mg/kg orally, every 24 hours

223.7.1.4.2

Enemas

Mild to moderate or recurrent episodes of constipation may require administration of enemas, manual extraction of impacted feces, or both. Several types of enema solutions may be administered, such as warm tap water (5 to 10 mL/kg), warm isotonic saline (5 to 10 mL/kg), dioctyl sodium sulfosuccinate (5 to 10 mL/cat), mineral oil (5 to 10 mL/cat), or lactulose (5 to 10 mL/cat). Enema solutions should be administered slowly with a well-lubricated 10 to 12F rubber catheter or feeding tube. Enemas containing

sodium phosphate are contraindicated in cats because of their propensity for inducing severe hypernatremia, hyperphosphatemia, and hypocalcemia in this species.[256]

223.7.1.4.3 Manual extraction

Cases unresponsive to enemas may require manual extraction of impacted feces. Cats should be adequately rehydrated and then anesthetized with an endotracheal tube in place to prevent aspiration should colonic manipulation induce vomiting. Water or saline is infused into the colon while the fecal mass is manually reduced by abdominal palpation. Sponge forceps may also be introduced rectally (with caution) to break down the fecal mass. It may be advisable to evacuate the fecal mass over a period of several days to reduce the risks of prolonged anesthesia and perforation of a devitalized colon. If this approach fails, colotomy may be necessary to remove the fecal mass. Laxative or prokinetic therapy (or both) may then be instituted once the fecal mass has been removed.

223.7.1.5 Laxative Therapy

Laxatives promote evacuation of the bowel through stimulation of fluid and electrolyte transport or increases in propulsive motility. They are classified as bulk-forming, emollient, lubricant, hyperosmotic, or stimulant laxatives according to their mechanism of action. Hundreds of products are available for the treatment of constipation. Table 223-7 summarizes those products that have been used with some success in cats.

223.7.1.5.1 Bulk-forming laxatives

Most of the available bulk-forming laxatives are dietary fiber supplements of poorly digestible polysaccharides and celluloses derived principally from cereal grains, wheat bran, and psyllium. Some constipated cats will respond to supplementation of the diet with one of these products, but many require adjunctive therapy (e.g., other types of laxatives or colonic prokinetic agents). Dietary fiber is preferable because it is well tolerated, more effective, and more physiologic than other laxatives. Fiber is classified as a bulk-forming laxative, although it has many other properties. The beneficial effects of fiber in constipation include increased fecal water content, decreased intestinal transit time, and increased frequency of defecation.[26,257] Fiber supplemented diets are available commercially, or the pet owner may wish to add psyllium (1 to 4 teaspoon per meal), wheat bran (1 to 2 tablespoon per meal), or pumpkin (1 to 4 tablespoon per meal) to canned cat food. Cats should be well hydrated before commencing fiber supplementation to maximize the therapeutic effect. Fiber supplementation is most beneficial in mildly constipated cats, prior to the development of obstipation and megacolon. In obstipated and megacolon cats, fiber may in fact be detrimental. Low-residue diets may be more beneficial in obstipated and megacolonic cats.

1404
1405

223.7.1.5.2 Emollient laxatives

Emollient laxatives are anionic detergents that increase the miscibility of water and lipid in digesta, thereby enhancing lipid absorption and impairing water absorption. Dioctyl sodium sulfosuccinate and dioctyl calcium sulfosuccinate are examples of emollient laxatives available in oral and enema form. Anecdotal experience suggests that dioctyl sodium sulfosuccinate therapy may be most useful in animals with acute but not chronic constipation. As with bulk-forming laxatives, animals should be well hydrated before emollient laxatives are administered. It should be noted that clincial efficacy has not been

definitively established for the emollient laxatives. Dioctyl sodium sulfosuccinate, for example, inhibits water absorption in isolated colonic segments *in vitro*, but it may be impossible to achieve tissue concentrations great enough to inhibit colonic water absorption *in vivo*. Dioctyl sodium sulfosuccinate at a dose of 30 mg/kg/day had no effect on fecal consistency in beagle dogs.[258] Further studies are required to determine the clinical efficacy and therapeutic role of dioctyl sodium sulfosuccinate in the management of the constipated cat.

223.7.1.5.3 Lubricant laxatives

Mineral oil and white petrolatum are the two major lubricant laxatives available for the treatment of constipation. The lubricating properties of these agents impede colonic water absorption and permit greater ease of fecal passage. These effects are usually moderate, however, and, in general, lubricants are beneficial only in mild cases of constipation. Mineral oil use should probably be limited to rectal administration because of the risk of aspiration pneumonia with oral administration, especially in depressed or debilitated cats.

223.7.1.5.4 Hyperosmotic laxatives

This group of laxatives consists of the poorly absorbed polysaccharides (e.g., lactose, lactulose), the magnesium salts (e.g., magnesium citrate, magnesium hydroxide, magnesium sulfate), and the polyethylene glycols. Lactose is not effective as a laxative agent in all cats.[259] Lactulose is the most effective agent in this group. The organic acids produced from lactulose fermentation stimulate colonic fluid secretion and propulsive motility. Lactulose administered at a dose of 0.5 mL/kg body weight every 8 to 12 hours fairly consistently produces soft feces in the cat. Many cats with recurrent or chronic constipation have been well managed with this regimen of lactulose. The dose may have to be tapered in individual cases if flatulence and diarrhea become excessive. Magnesium salts are not currently recommended in the treatment of feline constipation and idiopathic megacolon. Some veterinarians have reported anecdotal successes with the polyethylene glycols.

223.7.1.5.5 Stimulant laxatives

The stimulant laxatives (bisacodyl, phenolphthalein, castor oil, cascara, senna) are a diverse group of agents that have been classified according to their ability to stimulate propulsive motility. Bisacodyl, for example, stimulates NO-mediated epithelial cell secretion and myenteric neuronal depolarization.[260] Diarrhea results from the combined effect of increased mucosal secretion and colonic propulsion. Bisacodyl (at a dose of 5 mg orally, every 24 hours) is the most effective stimulant laxative in the cat. It may be given individually or in combination with fiber supplementation for long-term management of constipation. Daily administration of bisacodyl should probably be avoided, however, because of injury to myenteric neurons with chronic use.[250]

223.7.1.6 Colonic Prokinetic Agents

Previous studies of feline colonic smooth muscle function have suggested that stimulation of colonic smooth muscle contraction might improve colonic motility in cats affected with idiopathic dilated megacolon.[252,253,261] Unfortunately, many of the currently available GI prokinetic agents have not proved useful in the therapy of feline constipation, either because of significant side effects (e.g., bethanechol) or

because the prokinetic effect is limited to the proximal GI tract (e.g., metoclopramide, domperidone, erythromycin). The 5-HT_4 serotonergic agonists (e.g., cisapride, prucalopride, tegaserod, mosapride) appear to have the advantage of stimulating motility from the gastroesophageal sphincter to the descending colon with relatively few side effects. Cisapride, for example, increases gastroesophageal sphincter pressure, promotes gastric emptying, and enhances small intestinal and colonic propulsive motility.[262] Cisapride enhances colonic propulsive motility through activation of colonic neuronal or smooth muscle 5-HT receptors in a number of animal species.[263,264] *In vitro* studies have shown that cisapride stimulates feline colonic smooth muscle contraction,[253,264] although it has not yet been conclusively shown that cisapride stimulates feline colonic propulsive motility *in vivo*. A large body of anecdotal experience suggests that cisapride is effective in stimulating colonic propulsive motility in cats affected with mild to moderate idiopathic constipation; cats with long-standing obstipation and megacolon are not likely to show much improvement with cisapride therapy. Cisapride was widely used in the management of canine and feline gastric emptying, intestinal transit, and colonic motility disorders throughout most of the 1990s.[262,265,266] Cisapride was withdrawn from the American, Canadian, and certain Western European countries in July 2000 after reports of untoward cardiac side effects in human patients. Cisapride causes QT interval prolongation and slowing of cardiac repolarization via blockade of the rapid component of the delayed rectifier potassium channel (I_{Kr}).[267] This effect may result in a fatal ventricular arrhythmia referred to as *torsades de pointes*. Similar effects have been characterized in canine cardiac Purkinje fibers,[267] but *in vivo* effects have not yet been reported in dogs or cats. The withdrawal of cisapride has created a clear need for new GI prokinetic agents, although cisapride continues to be available from compounding pharmacies throughout the United States. Two new prokinetic agents, tegaserod and prucalopride, are in differing stages of drug development and may prove useful in the therapy of GI motility disorders of several animal species.[261]

Tegaserod is a potent partial nonbenzamide agonist at 5-HT_4 receptors and a weak agonist at 5-HT_{1D} receptors.[269,270] Tegaserod has definite prokinetic effects in the canine colon, but it has not yet been studied in the feline colon. Intravenous doses of tegaserod (0.03 to 0.3 mg/kg) accelerate colonic transit in dogs during the first hour after intravenous administration.[269] Tegaserod at doses of 3 to 6 mg/kg orally has also been shown to normalize intestinal transit in opioid-induced bowel dysfunction in dogs,[271] and it may prove useful in other disorders of intestinal ileus or pseudo-obstruction. Gastric effects of tegaserod have not been reported in the dog, so this drug may not prove as useful as cisapride in the treatment of delayed gastric emptying disorders. *In vitro* studies suggest that tegaserod does not prolong the QT interval or delay cardiac repolarization as has been occasionally reported with cisapride. Tegaserod was marketed under the trade name of Zelnorm in the United States in September 2002 for the treatment of constipation-predominant IBS in women. As with many other drugs in companion animal medicine, tegaserod has not been licensed for the treatment of canine or feline GI motility disorders.

1405

1406

Prucalopride is a potent 5-HT_4 receptor agonist that stimulates GMCs and defecation in the dog and cat.[272,273] Prucalopride also appears to stimulate gastric emptying in the dog.[274] In lidamidine-induced delayed gastric emptying in dogs, prucalopride (0.01 to 0.16 mg/kg) dose-dependently accelerates gastric emptying of dextrose solutions. Prucalopride has not yet been marketed in the United States or elsewhere.

Misoprostol is a prostaglandin E_1 analogue that reduces the incidence of nonsteroidal anti-inflammatory drug (NSAID)-induced gastric injury. The main side effects of misoprostol therapy are abdominal discomfort, cramping, and diarrhea. Studies in dogs suggest that prostaglandins may initiate a giant

migrating complex pattern and increase colonic propulsive activity.[275] *In vitro* studies of misoprostol show that it stimulates feline and canine colonic smooth muscle contraction.[276] Given its limited toxicity, misoprostol may be useful in cats (and dogs) with severe refractory constipation.

Ranitidine and nizatidine, classic histamine H_2 receptor antagonists, may also stimulate canine and feline colonic motility. These drugs stimulate contraction apparently through inhibition of tissue acetylcholinesterase and accumulation of acetylcholine at the motor endplate. It is not yet clear how effective these drugs are *in vivo*, although both drugs stimulate feline colonic smooth muscle contraction *in vitro*.[277] Cimetidine and famotidine, members of the same classification of drug, are without this effect.

223.7.1.7 Surgery

Colectomy should be considered in cats that are refractory to medical therapy (Figure 223-13; see Surgery). Cats have a generally favorable prognosis for recovery after colectomy, although mild to moderate diarrhea may persist for weeks to months postoperatively in some cases.[278,279] Although pathologic hypertrophy may be reversible with early pelvic osteotomy in some cases,[255] subtotal colectomy is an effective treatment for this condition regardless of duration, and pelvic osteotomy is not required.[280]

Figure 223-13 Surgical appearance of feline idiopathic megacolon.

223.7.1.8 Prognosis

Many cats have one or two episodes of constipation without further recurrence, although others may progress to complete colonic failure. Cats with mild to moderate constipation generally respond to conservative medical management (e.g., dietary modification, emollient or hyperosmotic laxatives, colonic prokinetic agents). Early use of colonic prokinetic agents (in addition to one or more laxative agents) is likely to prevent the progression of constipation to obstipation and dilated megacolon in these cats. Some

cats may become refractory to these therapies, however, as they progress through moderate or recurrent constipation to obstipation and dilated megacolon. These cats eventually require colectomy. Cats have a generally favorable prognosis for recovery after colectomy, although mild to moderate diarrhea may persist for 4 to 6 weeks postoperatively in some cases.

223.7.2 Irritable Bowel Syndrome

A fiber-responsive large bowel diarrheal syndrome similar to IBS in humans has been characterized in dogs.[185] Affected animals have a chronic idiopathic large bowel-type diarrhea characterized by excessive fecal mucous, hematochezia, and tenesmus. Pet owners occasionally report abdominal pain and weight loss. Multiple diet changes and empiric medications fail to relieve clinical signs. Medical investigation is negative for bacterial and other pathogens, colitis, and colonic neoplasia, and the term *chronic idiopathic large bowel diarrhea* is applied to the patient's disorder. Dogs affected with this syndrome may respond to the feeding of a highly digestible diet that is supplemented with soluble fiber.[185] Dogs that have failed to respond to fiber supplementation may respond to medical treatment with loperamide or anticholinergic agents.[187]

223.8 ULCER

223.8.1 Cause

Colonic ulcers may develop after glucocorticoid therapy and neurosurgery in dogs with spinal cord injury.[281,282] Gastric ulcers are of greater prevalence in this circumstance, but colonic ulcers may be equally devastating. Several factors are likely to contribute to colonic ulcerogenesis, including glucocorticoid-induced inhibition of immune function, epithelial renewal, prostaglandin production, mucus secretion, and collagen production; neurosurgery-induced increases in sympathetic tone; and the inhibitory effects of spinal injury on colonic motility and blood flow. The risk of colonic ulcer formation is greatly increased by concurrent NSAID administration. Why this lesion develops in some dogs but not others is not readily explained.

223.8.2 Pathophysiology

The left colic flexure or proximal portion of the descending colon appears to be at greatest risk for colonic ulceration and perforation; two thirds of the published cases were reported at this site.[282] Nonambulatory neurosurgical patients treated with dexamethasone are at greatest risk for development of colonic perforation. Colonic perforation is often preceded by variable nonspecific signs, most frequently depression, anorexia, and emesis. Perforation appears to be associated with 100% mortality, emphasizing the importance of prevention and early clinical recognition.

223.8.3 Clinical Examination

Middle-aged, male dogs are most often affected, usually within 5 to 7 days of surgery. Depression, anorexia, emesis, abdominal pain, constipation, melena, and fever are the most important clinical signs. Many of these signs are subtle and easily missed by some pet owners. The immunosuppressive properties of glucocorticoids may mask the initial signs of peritonitis associated with colonic perforation.

223.8.4 Diagnosis

If suspected, patients at risk should be carefully evaluated for perforation and peritonitis. Imaging studies (radiography and ultrasonography), abdominocentesis, peritoneal lavage, and exploratory surgery, if indicated, should be considered in patients at risk.

223.8.5 Treatment

Patients with colonic ulcer, perforation, and peritonitis should be explored immediately. Therapy should be aimed at excision of the ulcer, anastomosis of healthy bowel segments, lavage of the peritoneal cavity, open peritoneal drainage (if indicated), and postoperative antibiotics.

223.8.6 Prognosis

Colonic ulcer and perforation is generally associated with a poor prognosis. A preventive approach to this complication appears to be warranted in high-risk patients: (1) use of less-potent glucocorticoids (e.g., prednisone, prednisolone) instead of dexamethasone, (2) limited or no use of glucocorticoids.

223.9 SURGERY

223.9.1 Indications

In dogs the most frequent indication for colonic and rectal surgery is either neoplastic disease or rectal prolapse. Other conditions, including cecal neoplasia, cecocolic volvulus, colonic entrapment, congenital anomalies, traumatic perforation, and perforation associated with intervertebral disc disease and corticosteroid treatment are less common indications for large intestinal surgery.[283] The most frequent indications for colonic surgery in cats is intractable megacolon.

223.9.2 Preoperative Considerations

In dogs with rectal or colonic tumors, appropriate staging is vital to determine the extent of local and systemic disease. In many cases, a careful digital rectal examination can delineate the extent of local disease in the rectum and provide subjective information on the enlargement of regional lymph nodes. Thoracic radiographs are made to rule out pulmonary metastatic disease. Abdominal ultrasonography is used to rule out abdominal metastatic disease and to guide aspiration and biopsy of enlarged iliac lymph nodes. Proctoscopy and colonoscopy show the local extent of neoplastic disease. It is vital that the entire colon be assessed with colonoscopy even after a rectal tumor has been identified, because additional neoplasms are reported in the colon in a percentage of these cases.[235,284] Preparation for evaluation and biopsy of the rectum and colon is performed using an orally administered GI lavage solution.[60,61]

Animals with anal or rectal prolapse are carefully examined to determine the underlying cause of tenesmus. In younger animals, parasitism is the most frequent predisposing cause identified. In older animals, tumors, colitis, urolithiasis, dystocia, and perineal herniation have all been associated with rectal prolapse.[284,285]

Mechanical cleansing is recommended before surgery of the large intestine in humans.[286] However, in cats undergoing surgery for megacolon, preoperative enemas are probably unwarranted because they create a liquid slurry that oozes through noncrushing clamps and contaminates the surgical field. Instead, the dry, hard feces associated with chronic constipation can easily be manipulated into the segment of colon to be resected and then removed. Preoperative enemas are contraindicated in cases of suspected large intestinal perforation.

Perioperative antibiotics are administered to minimize the chance of surgical infection. Randomized, controlled clinical trials of antimicrobial prophylaxis in canine and feline colonic surgery have not been conducted. However, based on human trials,[287] antibiotics effective against aerobes and especially the anaerobes that predominate in the large intestine are administered intravenously once at the beginning of surgery. Antibiotics are not administered again unless either contamination occurs at surgery or the procedure takes longer than 2 hours. In the latter case a second intravenous dose of antibiotics is administered. Antibiotics are continued postoperatively in cases with preoperative or surgical contamination based on the results of operative culture and sensitivity testing.

223.9.3 Surgical Considerations

In animals requiring surgery for cecal or colonic disease, a ventral midline laparotomy is performed. After conducting a thorough abdominal exploration for concurrent or metastatic disease, the affected area of the large intestine is packed off with moistened laparotomy sponges. Resection of the cecum can be performed with or without preservation of the ileocolic junction, depending on the extent of the local disease. In most cases of cecal neoplasia a complete resection and jejuno-or ileocolonic anastomosis is performed to ensure adequate tumor removal.

Subtotal colectomy is an effective treatment for feline idopathic megacolon or megacolon secondary to the mechanical obstruction created by old, healed pelvic fractures. Recommendations for removal of the ileocolic valve and ileum vary in cats with megacolon. The ileocolic blood vessels tether the distal ileum and proximal ascending colon, preventing anastomosis to the distal colon; therefore if a complete colectomy is performed, these vessels must be sacrificed. This necessitates removing the ileum, which has important normal functions in water, vitamin B_{12}, and bile salt resorption, and performing a jejunocolonic anastomosis. In spite of this concern, postoperative intestinal function was normal in four cats evaluated after subtotal colectomy and jejunocolonic anastomosis.[279] The ileocolic valve also minimizes colonic bacterial access to the small intestine,[288] so preservation of the valve would be ideal to minimize small intestinal bacterial overgrowth and deconjugation of bile salts. However, preservation of the ileocolic junction necessitates leaving several centimeters of the ascending colon to ensure a tension-free anastomosis, possibly predisposing these cats to recurrent constipation. To evaluate these concerns, cats with megacolon treated with colectomy were studied retrospectively. Cats with excision of the ileocolic junction had significantly looser stool on long-term follow-up.[289] However, there was no difference in the incidence of constipation between cats with preservation versus excision of the ileocolic junction.[289] This is perhaps explained by *in vitro* experiments with ascending and descending colonic smooth muscle from cats with clinical megacolon showing that smooth muscle dysfunction is less severe in the ascending colon.[254]

When the ileocolic junction is preserved, the ascending colon is transected approximately 3 cm distal to the ileocolic junction to ensure a tension-free anastomosis. An end-to-end colocolostomy is performed using single interrupted sutures of 4/0 polydioxanone.[283] The omentum is wrapped around the anastomotic site and

the abdomen is thoroughly lavaged with a warm, balanced electrolyte solution. All lavage fluid is aspirated from the peritoneal cavity before the incision is closed.

1407

1408

Prior to surgery, rectal prolapse must be differentiated from a prolapsed intussusception of intestine or colon. A well-lubricated, blunt instrument is passed between the anus and the prolapsed tissue. In animals with a prolapsed intussusception, the probe passes easily. Conversely, in animals with a simple rectal prolapse, the probe cannot pass because the prolapsed tissue joins the mucocutaneous junction of the anus.[284] The viability of the prolapsed tissue is assessed based on gross appearance, color, and bleeding. In cases of simple prolapse where the tissue is healthy, the prolapse is digitally reduced and a purse string suture is inserted in the mucocutaneous junction of the anus, avoiding the anal sacs and the anal sac ducts. The suture is tightened sufficiently to prevent prolapse while leaving a small orifice for the passage of soft feces. The suture is removed after several days and the animals carefully observed for recurrence of the prolapse. In cases of recurrent or substantial prolapse where the rectal tissue is still healthy, a colopexy is performed. Rectal resection is performed in animals with traumatized, necrotic, or irreducible rectal prolapse. The reader is referred elsewhere for the details of these procedures.[284]

Various techniques and surgical approaches have been described for removal of rectal tumors.[284] The approach and technique vary with the extent and location of the mass or masses. Tumors in the proximal rectum may be accessed by a ventral midline laparotomy combined with a pelvic osteotomy. Healing of the distal colon, the proximal rectum, or both is complicated by the poor blood supply to this area of the large intestine.[290] A dorsal approach has been described for tumors involving the middle third of the rectum,[284,291] however, many tumors in this area are also amenable to resection via a rectal pull-through.[284,292] The plexus of pelvic nerves at the peritoneal reflection is vital to postoperative fecal continence. In an experimental study on healthy dogs, transection alone or resection of 4 cm of rectum via a dorsal approach resulted in fecally continent dogs. Resection of 6 cm of the rectum, including the peritoneal reflection, caused fecal incontinence.[291] This limitation on resection is problematic in animals with larger rectal tumors, as a 2 cm gross margin is recommended on both sides of the tumor.[284]

223.9.4 Postoperative Considerations

Postoperative treatment depends largely on the underlying reason for cecal, colonic, or rectal surgery. Pre-or postoperative epidural anesthesia using a combination of local anesthetic and narcotic provides effective pain relief. Animals receiving epidural anesthesia may not be able to urinate normally for 12 to 24 hours; hence bladder size must be evaluated frequently and the bladder gently expressed or catheterized if needed. Narcotics, mixed narcotic agonists and antagonists, partial mu opioid agonists, and COX-II inhibitory class NSAIDS are alternatives for pain management in dogs. Mixed narcotic agonists and antagonists are effective in cats.

Cats recovering from colectomy are maintained on intravenous fluids until they commence eating and drinking. Electrolytes are supplemented if necessary. Bowel movements may be soft or loose and more frequent than normal. A highly digestible, low residue diet is fed. In cats with profuse postoperative diarrhea in which small intestinal bacterial overgrowth is suspected, a short course of antibiotics is administered.

Adequate nutrition is vital for dogs and cats recovering from large intestinal surgery. Early feeding increases anastomosis strength and promotes enteric epithelial proliferation and function.[293,294] Ideally, the diet should provide a source of soluble fiber which, when hydrolyzed to SCFAs, stimulates colonic mucosal

proliferation.[293] In animals with fecal continence difficulties after extensive rectal resection, a low-residue diet is fed twice daily. The animal is then walked for 20 to 30 minutes after eating. In many cases the gastrocolic reflex will result in defecation and near complete emptying of the colon during this time, minimizing subsequent fecal soiling in the house.

224 CHAPTER • 224 Rectoanal Disease

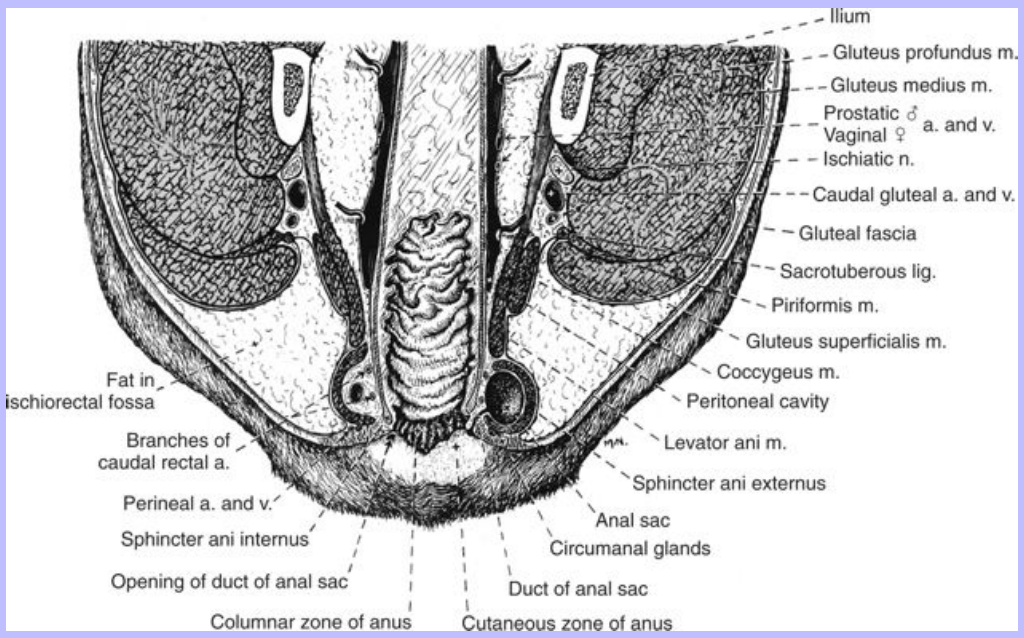
Debra L. Zoran

The storage and voluntary evacuation of feces are under the control of the muscles and nerves serving the pelvic canal, rectum, and anus. These elimination functions are controlled by complex interactions involving smooth muscles, striated muscles, and the intrinsic and extrinsic neurons that innervate them. The ability to retain fecal content, to perceive that the rectum is full, and to determine appropriate defecation is called *fecal continence*. Abnormal function of these muscles or nerves results in loss of fecal continence or constipation but rarely leads to hematochezia or mucoid diarrhea. Alternatively, inflammatory disorders of the rectal mucosa result in tenesmus, increased fecal mucus, hematochezia, or frequent defecation. In dogs with severe rectal inflammatory disease, fecal incontinence may occur secondary to reservoir function failure. Even though many of these conditions are not as serious as other diseases of the gastrointestinal (GI) tract, their social impact makes them a significant influence on the human-animal bond and on the owners' willingness to manage their pet's condition.

224.1 ANATOMY

The rectum, anal canal, internal and external anal sphincters, muscles of the pelvic canal, and the skin and subcutaneous structures of the perianal region make up the anorectum (Figure 224-1).[1] The rectum originates at the pelvic inlet, a continuation of the distal colon, and ends at the anal canal.[1] The rectal muscularis layer includes the longitudinal muscles, which are continuous with the muscularis layers of the colon, and the inner circular muscle layer. The two layers, which provide tone and structural support for the rectal mucosa and submucosa, are controlled and supported by the myenteric plexus neurons and the caudal rectal arteries, respectively.[2] The rectal mucosa contains columnar epithelium rich in goblet cells and numerous solitary lymph follicles. The secretion of mucus from goblet cells is regulated by a submucosal neuronal plexus in the rectal mucosa.[2] Inflammation of the mucosa causes stimulation of this neuronal plexus, resulting in the clinical signs of anorectal disease (e.g., mucoid feces, hematochezia, tenesmus, and dyschezia). As with Peyer's patches in the small intestine, these lymph follicles can be visualized endoscopically as either raised or punctuate depressions in the rectal mucosa. At the junction of the rectum and anus, the mucosal epithelium transitions to squamous epithelium. This transition point defines the junction of the rectum and the internal and external anal sphincters.

Figure 224-1 Cross section through the anorectum of a dog. (From Evans HE: Miller's Anatomy of the Dog, 3rd ed. Philadelphia, WB Saunders, 1993.)



The short anal canal extends from the rectum to the anal opening and forms the terminal opening of the alimentary canal. The involuntary smooth muscle of the internal anal sphincter and striated skeletal muscle of the voluntary external anal sphincter surround the anal canal and determine its function. The mucosa of the anal canal is divided into three zones, the columnar, intermediate, and cutaneous zones.[2] The columnar zone connects the rectum to the anus and is composed of longitudinal ridges of columnar mucosa. The intermediate zone is the transition area between the columnar mucosa and the stratified squamous epithelium that makes up the cutaneous zone. The cutaneous zone is the most caudal portion of the anus and is subdivided into two regions. The innermost region contains the paired anal sacs, which lie ventrolateral to the anus, and the termination of the anal sac ducts.[2] The outermost region is keratinized and hairless and peripheral to the anus itself. The anal opening is formed by the plane that separates the two cutaneous zones. The anal sacs contain coiled, apocrine, sudoriparous glands and a few sebaceous glands.[2,3] The secretions from these glands, which are serous to pasty in composition, accumulate in the anal sacs, along with desquamated epithelium and bacteria. Anal sacs are of clinical importance because they may become impacted with secretions, which often causes discomfort and sometimes leads to infection or abscessation.

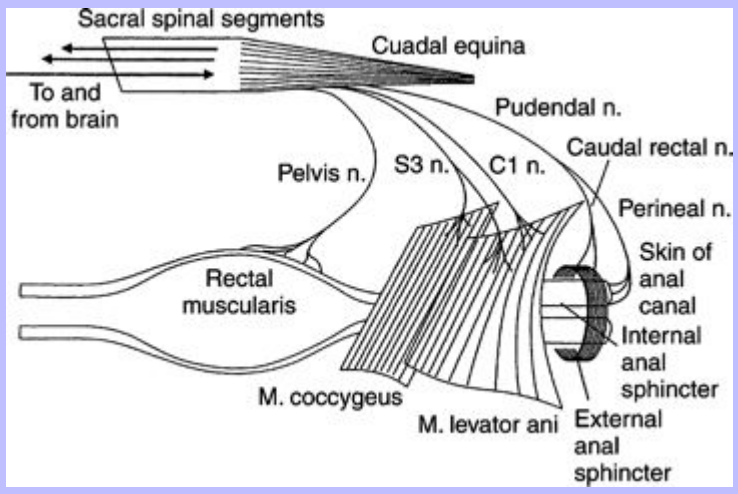
Two other types of glands present in the anal area. *Circumanal (hepatoid) glands* are nonsecretory, subcutaneous sebaceous glands in the anal subcutaneous zone.[2,3] These glands may become clinically important in intact male dogs, because they grow throughout life and form adenomas late in life as a result of constant androgen exposure. The *anal glands* are tubuloalveolar sweat glands located craniolateral to the circumanal glands.[2,3] The anal

glands produce a fatty secretion, the function of which is unknown. The ducts from these glands open in the intermediate zone of the anus.

The innervation of the anorectum is similar to that of the colon in that it comprises a well-defined enteric nervous system consisting of a myenteric and a submucosal plexus.[2] This segment of the autonomic nervous system controls the many sensory, integrative, and motor neurons that characterize the functions of the rectum and anus (Figure 224-2).[1] In particular, these neurons control the secretions of goblet cells and integrate movements of the colon and rectum to ensure appropriate storage and transport of feces. The innervation of the anus is more complex. The pelvic plexus, specifically the sacral nerve branches of the pelvic nerve, provides parasympathetic fibers that are excitatory to the rectum and inhibitory to the internal anal sphincter.[2,4] Conversely, the sympathetic fibers that arise from the hypogastric nerves of the caudal mesenteric ganglion are inhibitory to the rectum (i.e., cause relaxation) and excitatory to the internal anal sphincter (i.e., cause contraction), thus allowing appropriate storage of feces.[2,4]

Relaxation of the internal and external anal sphincters in conjunction with rectal contraction permits defecation. The external anal sphincter is a striated muscle with several muscle bundles that surround the internal sphincter. 1409
These muscles are reflexively able to increase anal sphincter pressure, mediated via somatic nerve fibers in the 1410
anal branch of the pudendal nerve, while still allowing accommodation of feces in the rectum.[2,4] A properly functioning external anal sphincter allows maximal distention (e.g., storage of feces in the rectum) while maintaining anal control. When the pudendal nerve is damaged, the external anal sphincter is incompetent, and clinically apparent fecal incontinence develops.

Figure 224-2 Neural control of defecation. (From Strombeck DR, Guilford WG: Small Animal Gastroenterology, 2nd ed. Davis, California, Stonegate Publishing, 1990.)



The pelvic diaphragm constitutes the final aspect of anatomic control of anorectal function. These muscles support the rectal and anal canal and participate in the maintenance of fecal continence and appropriate defecation by providing structural support and additional muscular control. The muscles that participate in this activity include the right and left ventral sacrococcygeal muscles and the levator ani.[2] The sacrococcygeal

muscles originate on either side of the rectum and attach dorsally to the base of the tail (see Figure 224-1).[1] These smooth muscles, which are innervated by the pelvic plexus, shorten the rectum during defecation, assisting in the evacuation of feces. The levator ani muscles are striated muscles (innervated by the sacral and caudal nerves) that surround the rectum and assist in compression of the rectum during defecation.[2]

224.2 PHYSIOLOGY OF DEFECATION

Normal anorectal function and the act of defecation are primarily pressure-based functions that rely heavily on complex interactions between peripheral pressure receptors, myenteric neurons, somatic and autonomic afferent nerve fibers, spinal cord, brain stem, somatic and autonomic efferent nerve fibers, and smooth and striated muscle of the rectum and anal sphincters[1,5–7] (see Figure 224-2). When the rectum is empty, intraluminal rectal pressure is low. Increased intraluminal pressure is the primary component of maintenance of fecal continence; it is generated by contraction of the internal anal sphincter, either in response to a sudden increase in intra-abdominal pressure (e.g., coughing or sneezing) or by an increase in rectal filling.[1,5] The main stimulus for defecation is increased pressure in the rectum caused by distention. The rectoanal inhibition reflex allows relaxation of the internal anal sphincter, along with contractions of the external anal sphincter, to allow slow but continuous filling of the rectum.[1,5,8] As the fecal volume increases in the rectum, conscious awareness of rectal filling is perceived by means of sensory signaling of information transmitted via sacral afferent fibers to the cerebral cortex.[4,6,9] The rectoanal inhibition reflex allows continued filling of the rectum until defecation is appropriate. If the volume of feces remains small (and stretch is minimal) or if defecation is not appropriate, the internal anal sphincter returns to a state of contraction, resulting in propulsion of feces back into the colon. This activity is also stimulated by descending inputs from motoneurons in the sacral spinal cord and pudendal nerve that mediate voluntary contraction of the external anal sphincter and levator ani.[4,6,9,10] This back-and-forth process is repeated until the volume of feces is sufficient both to initiate rectal distention and to come into contact with the anal mucosa, resulting in a stronger urge to defecate.

When defecation is initiated, distention of the rectum activates parasympathetic efferents that control contraction of colonic smooth muscle (resulting in mass movement of the distal colon) and inhibition of the external anal sphincter and pelvic muscles (resulting in relaxation of the sphincters).[11–13] The rectum itself produces only small contractions that are not propulsive, therefore the main propulsive force for expelling feces from the body is the contraction of colonic smooth muscles. Thus the rectum serves primarily as a conduit during the process of defecation and as a storage depot in the periods between. Defecation is facilitated by proper posture and generation of increased abdominal pressure (closure of the glottis, fixation of the diaphragm, and contraction of the abdominal wall muscles).[2,5,12,13] Conscious suppression of defecation is facilitated by descending impulses to sacral nerves and the pudendal nerve, which mediate contraction of the levator ani and external anal sphincter, resulting in maintenance of fecal continence.[9,12,13]

224.3 HISTORY AND PHYSICAL EXAMINATION

The close association of the anorectum and colon results in similar clinical signs of disease for these two components and creates difficulty in localizing signs to a specific region of the lower GI tract. A careful history and complete physical examination are required to determine whether tenesmus and dyschezia are the result of colonic disease or of anorectal disease alone. In general, diseases of the anorectum are either inflammatory (with signs of hematochezia, tenesmus, mucoid feces, or dyschezia predominating) or they result in altered motility (e.g., constipation or fecal incontinence). It is unusual for systemic signs, such as anorexia, weight loss, vomiting,

or diarrhea, to occur in animals with rectoanal disease; their occurrence suggests concurrent systemic disease or disorders in other segments of the GI tract.

The physical examination of the perineum should always include careful visual inspection for evidence of inflammation, swelling, tumor masses, herniation, rectoanal prolapse, or fistulas. After the visual inspection a digital examination should be performed, including palpation of the anal sphincter tone, the pelvic diaphragmatic musculature, and the size and expressibility of the anal sacs; determination of the diameter of the rectal lumen; and tactile examination of the texture, regularity, and surface of the mucosa. Other structures that should be palpated are the prostate in males, the vaginal vault in females, and the pelvic urethra. In pets with severe inflammation of the anorectum, digital palpation may be impossible without sedation or complete anesthesia. In general, cats should be sedated prior to rectoanal palpation to prevent patient or operator injury.

Hematochezia, blood dripping from the anus, or excess mucus with normally formed feces is often a good indicator of rectoanal disease, especially inflammatory diseases such as proctitis, perianal fistulas, anal sacculitis, polyps, or neoplasia. Tenesmus is a hallmark of both anorectal and colonic disease and must be differentiated from *dyschezia* (painful defecation), which is much more typical of diseases of the anorectum. Both conditions are typically associated with inflammatory diseases of the colon or anorectum; they result in increased frequency and urgency of defecation and straining during defecation (Box 224-1).[14] Because many owners may confuse the signs of dyschezia and tenesmus, it is often necessary to observe the animal during the act of defecation. Furthermore, owners often are unable to determine whether straining is associated with defecation or urination, therefore urogenital disease must be considered until the clinical signs can be localized.

1410

1411

224.3.1 Box • 224-1 Causes of Tenesmus and Dyschezia

224.3.1.1 Colorectal Disease

Constipation

Colitis-proctitis

Inflammatory bowel disease

Histoplasma capsulatum (histoplasmosis)

Clostridium perfringens (enterotoxicosis)

Prototheca zopfii (protothecosis)

Rectal stricture

Neoplasia–polyps

Foreign material

Irritable bowel syndrome

224.3.1.2 Perineal-Perianal Disease

Anal sacculitis, impaction, or abscess

Anal sac neoplasia

Perianal fistula

Perineal hernia

224.3.1.3 Urogenital Disease

Cystitis-urethritis-vaginitis

Cystitis–urethral calculi

Prostatitis–prostatic abscess

Parturition

Neoplasia of the urethra, bladder, prostate, or vagina

224.3.1.4 Miscellaneous Causes

Caudal abdominal cavity mass

Pelvic fracture–neoplasia

In most cases of anorectal disease, routine hematology and biochemical tests are seldom helpful for identifying a specific diagnosis. However, they are important in the identification of concurrent or complicating conditions that may influence further diagnostic tests or therapy, especially in older animals. In any animal with an abnormal fecal stream, multiple fecal flotations, cytologic examination of feces, and specific tests for infectious causes of GI disease (e.g., enzyme-linked immunosorbent assay [ELISA] for clostridial toxin, *Giardia* spp., cryptosporidia, and viruses) are strongly recommended. The most common parasitic cause of tenesmus and hematochezia in dogs is *Trichuris vulpis* (whipworm) infection, and because of the pattern of intermittent shedding, empirical anthelmintic therapy is recommended even in the absence of identification of ova in feces.

In dogs and cats with acute onset of hematochezia and tenesmus, dietary therapy using high-fiber diets is a reasonable initial therapeutic approach. If further diagnostic evaluation is deemed necessary, specific imaging techniques directed toward assessment of the anorectum are indicated. Imaging of the anorectum by conventional means (e.g., abdominal radiography and ultrasonography) is generally unrewarding for most cases of anorectal disease. However, these modalities can be helpful for identifying some causes of colonic disease (e.g., neoplasia, infiltrative disease, constipation, or foreign bodies) that may have a similar clinical presentation. Intrarectal ultrasonography can help the examiner to determine the extent of intraluminal or intramural tumor involvement and to evaluate pararectal structures. However, ultrasound units with these probes are not universally available. Contrast radiography is rarely helpful in the diagnosis of anorectal disease, because most rectal strictures, polyps, or hernias can be either palpated or observed during proctoscopic examination. However, in dogs with severe rectal strictures or tumors that obstruct passage of a colonoscope or proctoscope, this technique may provide the examiner with additional information.

In general, rigid proctoscopy, with or without colonoscopy, is the diagnostic tool of choice for examination, biopsy and, in some cases, treatment of rectoanal disease. Proctoscopy is technically less difficult, and the instrumentation is less expensive, than that required for flexible colonoscopy. With either a proctoscope or colonoscope, the rectal mucosa can be visualized for color, texture, friability, masses, and bleeding, and biopsies of the colonic or rectal mucosa can be readily obtained. Furthermore, any lesions of the terminal rectum (e.g., polyps) that are identified can often be directly visualized by gently prolapsing the rectum and anus using tissue forceps. This technique also allows surgical removal of small polyps or masses.

224.4 DISEASES OF THE RECTUM

224.4.1 Perineal Hernia

Perineal hernias have been clinically recognized in the dog for more than 100 years and are most common in older, intact male dogs.[15,16] They are rarely seen in cats or female dogs.[17] Four types of perineal hernias have been described, but the most common type is the caudoventral perineal hernia, which occurs between the levator ani, external anal sphincter, and internal obturator muscles.[18,19] Sciatic hernias occur between the sacrotuberous ligament and the coccygeus muscle, dorsal hernias occur between the levator ani and coccygeus muscles, and ventral hernias occur between the levator ani and ischiourethralis or ischiocavernosus muscles.[19] Most perineal hernias are unilateral, although bilateral herniation can occur, with the right side being predisposed.[15,16] Herniation may involve only rectal tissues, but eventually prolapse of pelvic organs, such as the urinary bladder, prostate, or other abdominal tissues (e.g., fat, intestine), into the weakened area can occur. In dogs, neurogenic atrophy of the levator ani muscles, gender-based variations in pelvic muscle anatomy, and gonadal hormonal influence are all thought to be factors in the development of perineal hernias.[19] The degree of stretching and deviation of the rectal wall and the presence or absence of abdominal organs in the hernia are all factors that determine clinical signs.

224.4.1.1 History and Physical Examination

In more than 90% of affected dogs, perineal swelling and tenesmus are the most common clinical signs[15,18,19]; however, constipation, dyschezia, and hematochezia are also reported. Dysuria and stranguria accompany the signs of rectoanal disease if the bladder is retroflexed and trapped in the ischiorectal fossa. With longstanding bladder entrapment, azotemia and signs of renal failure (e.g., anorexia, vomiting) also occur. Less commonly, persistent dribbling of urine or other signs of urinary incontinence may be present instead of signs of urinary obstruction. In cats with perineal herniation, concurrent severe obstipation or megacolon is the most common predisposing factor.[17] The physical examination often reveals a visible perineal swelling or a reducible perineal swelling (Figure 224-3). External palpation of a defect in the musculature just lateral to the external anal sphincter is often sufficient for confirmation of the hernia. However, in some pets the hernia is palpated rectally only as a defect in the pelvic diaphragm. A digital examination can also be performed to detect any other rectal wall abnormalities (e.g., deviation, sacculation, or diverticulum). In general, the combination of historical and physical examination findings is sufficient to confirm the diagnosis of perineal hernia. Further evaluation, either with ultrasonography or contrast studies, may be necessary to determine the extent of hernia contents (e.g., the presence of intestine, bladder, or prostate) prior to repair. The major differential diagnoses are rectal diverticulum, neoplasia, prostatic or paraprostatic cyst, and seroma/hematoma.

Figure 224-3 Perineal swelling in an 8-year-old dog with a perineal hernia.

224.4.1.2 Pathogenesis

The pathogenesis of perineal hernias is not completely understood. Because most patients are older male dogs, gonadal hormonal influences have been strongly suggested. The evidence supporting this idea derives from the fact that castrated dogs are rarely affected with perineal hernia; however, no difference in the levels of testosterone and estrogen 17-beta have been found between normal dogs and dogs with perineal hernia.[20] Some have suggested that, rather than hormone concentrations, the number or affinity of hormone receptors may be the important factor in the development of perianal muscle weakness.[21] Another potential factor is that in male dogs, the levator ani muscles are weaker and thinner and have a weaker attachment to the external anal sphincter.[18,22,23] The fact that brachycephalic breeds (e.g., Boston terrier, boxer, Welsh corgi, and Pekinese) appear to be predisposed to the development of perineal hernias suggests that an anatomic or breed-specific defect is important.[19] Evidence against a strictly hormonal cause for hernia development is the fact that in cats, the benefits of castration have not been demonstrated, a finding illustrated by a retrospective study in which 19 of 20 cats with perineal hernias had been either castrated or spayed.[17]

Aside from anatomic and hormonal theories, another factor considered important in disease development is damage to the pudendal nerve or to the first, second, or third sacral nerves, which results in neurogenic atrophy of the levator ani muscles.[23] However, it is not known whether damage precedes development or occurs as a result of the hernia.

In addition to primary predisposing factors, perineal hernias in dogs may occur secondary to persistent tenesmus and constipation, which results in muscular weakness in the pelvic floor[15,16] or may occur as a result of severe prostatic disease or paraprostatic cysts.[24] In cats, perineal hernias most commonly occur secondary to constipation resulting from megacolon.[17] Other factors associated with perineal hernias in cats are perianal masses, chronic fibrosing colitis, and previous perineal urethrostomy.[17]

224.4.1.3 Therapy

Definitive surgical repair (perineal herniorrhaphy) is the treatment of choice in most instances. The primary aim of the surgical repair is to replace muscular support of the pelvic diaphragm. Preoperative preparations may include preanesthetic blood work, electrocardiography, abdominal ultrasound, and chest radiographs if indicated to rule out complicating factors for anesthesia or secondary causes of hernia formation. Stool softeners (e.g., lactulose) and a highly digestible diet (i.e., to reduce fecal volume) should be initiated several days before surgery.[19] If the bladder is retroflexed and trapped within the hernia, catheterization should be attempted immediately. If this is unsuccessful, the bladder should be emptied by cystocentesis; then, with the bladder decompressed, the hernia is reduced and the bladder is pushed back into the abdominal cavity if possible.

Regardless of whether the bladder is properly repositioned, a transurethral Foley urinary catheter should be placed and a closed collection system should be attached until surgery can be performed. Urine cultures should be obtained and appropriate antibiotics administered for all animals with perineal hernia involving bladder entrapment. Preoperative antibiotics (e.g., cefoxitin used as a single agent) are recommended for protection against contamination by enteric coliforms.

Several techniques for perineal hernia repair have been reported, including standard herniorrhaphy, transposition of the superficial gluteal muscle, an internal obturator transposition technique, a combination of the gluteal and obturator muscle transpositions, and a special technique in which small intestinal submucosa is used to repair the defect.[19,25–28] The reader is referred to a surgical text for a detailed description of the specific surgical techniques used in herniorrhaphy. Traditional hernia repair involves closure of the triangular area formed by the external anal sphincter, levator ani, coccygeus, and obturator muscles. However, with this method of repair, the rate of hernia recurrence is high (10% to 45%), and postoperative complications are common.[27]

The current standard for repair is the obturator transposition technique because of its much lower rate of recurrence and lower complication rate. The use of porcine small intestinal submucosa as a biomaterial for perineal herniorrhaphy is relatively new and has shown promise both as a primary means of repair and as an augmentation technique when the internal obturator muscle is weak or when a salvage procedure is required.[19,28] Other surgical procedures that may be required in the repair of this disorder include repair of diverticuli or rectal deviations, removal of prostatic cysts and, in cats with megacolon, a subtotal colectomy. Castration is recommended but is not an essential aspect of treatment, especially if the length of the procedure increases the risk for an older dog.

After surgery, a highly digestible (low residue) diet and stool softeners should be provided indefinitely to prevent straining and recurrence. Local perineal swelling is common and resolves with application of hot compresses. In dogs for which surgical repair is not possible, the treatment approach is to reduce fecal volume, impaction, and straining by feeding a low-residue diet and administering stool softeners, laxatives (e.g., lactulose), and enemas as needed. In most cases, dietary and conservative management of hernias is not rewarding in the long term.

224.4.1.4 Prognosis

In general, the prognosis for long-term repair of perineal hernias is guarded. The rates of recurrence are related to the type of surgical repair done and the skill of the surgeon. Most surgeons agree that the obturator transposition technique, combined with one of the other approaches, is the best surgical option currently available.[19,26,28] However, the more severe the preoperative clinical signs, the longer the signs have been present, and the existence of bilateral involvement all increase the likelihood of a higher recurrence rate, regardless of the technique used. Other postoperative complications include infection, seroma or hematoma formation, fecal incontinence, rectal prolapse (especially if a bilateral repair is required), sciatic nerve paralysis or sciatic pain, and urinary complications, including incontinence or obstruction (caused by sutures in or scarring of the urethra).[18,19]

224.4.2 Rectal Tumors

Tumors of the intestine, which are uncommon in dogs and cats, represent fewer than 1% of all malignancies reported.[29] In dogs, rectal or colonic adenocarcinoma is the most common malignant intestinal tumor, whereas adenomatous polyps of the rectum are the most common benign tumor.[29] Lymphoma is the most common intestinal tumor of cats, and although it occurs more frequently in the small intestine, colorectal lymphoma is the most common large bowel tumor of cats.[29] Lymphosarcoma of the rectum is less common in dogs than in cats, but it is more prevalent than colonic lymphosarcoma. Siamese cats are reported to have a higher incidence of intestinal (including colonic) adenocarcinoma, but in one study, domestic shorthair cats had a higher frequency of rectal adenocarcinoma than Siamese cats.[29,30] Other rectal tumor types that have been reported include leiomyoma, leiomyosarcoma, plasmacytoma, and fibrosarcoma.[29–33] Polyps that occur in the rectum are generally focal, pedunculated, or sessile and rarely metastasize, although they can in some instances invade locally into the lamina propria and submucosa.[1,29,34] In dogs, locally invasive polyps, although histologically benign, are referred to as *carcinoma in situ*.[29]

224.4.2.1 History and Physical Examination

The signalment of dogs and cats affected with rectal tumors is typical in that older dogs (mean, 9 years of age) and cats (mean, 10 years of age) are more likely to be affected.[29] In dogs the incidence is higher in males, whereas in cats the opposite is true.[29,35] Breeds predisposed to the development of intestinal cancers include boxers, collies, and German shepherds, and this appears to be true for rectal tumors as well.[29] The clinical signs seen in animals with rectal tumors include hematochezia, mucoid feces, tenesmus, and dyschezia of varying severity. Other clinical signs may be observed (e.g., weight loss, inappetence), depending on the tumor type, location, and behavior.

A digital rectal examination may reveal a prominent mucosal mass, narrowing of the rectal lumen, pain during the examination, or blood on the gloved finger. Rectal adenocarcinomas may have either a prominent mass or a stenotic annular ring lesion that encircles the rectum. If significant obstruction is present, colonic distention may be detected on abdominal palpation due to persistent constipation or incomplete evacuation of the bowel. Conversely, in animals with persistent straining, rectal prolapse may occur.

224.4.2.2 Diagnosis

Palpation of a rectal mass or annular ring stricture in a dog or cat with a typical signalment and clinical signs is often suggestive; however, biopsy of the affected tissue, either using proctoscopy or by direct visualization, is necessary to make the definitive diagnosis. In most cases a mucosal tissue biopsy is adequate for analysis; however, in some submucosal tumors (e.g., lymphosarcoma, leiomyosarcoma), an excisional biopsy or collection of deeper tissues is required. Radiography and ultrasound examination of the region and drainage of lymph nodes are very helpful for defining the depth of the lesion and staging the extent of metastasis.

224.4.2.3 Therapy

For all tumors of the rectum except lymphosarcoma, surgical excision of the cancer is the recommended initial course of action, because this provides patient relief and debulks the tumor mass.[29,35] For dogs with rectal lymphosarcoma, treatment with standard chemotherapy protocols is initiated unless a mass is obstructing the rectum and debulking is necessary.[29]

Radiation therapy, cryosurgery, and laser therapy have all been used to treat colorectal tumors after surgical excision, with variable success.[36–39] Electrosurgery or cryosurgery is recommended for dogs with nonannular masses or polyps that can be easily prolapsed. Full-thickness resection of annular rectal cancers can be attempted, but wound dehiscence, infection, rectal stricture, and fecal incontinence are common complications.

More recently, local excision combined with cryosurgery has been used to extend the life of affected dogs significantly; however, the complication rate (e.g., for strictures, prolapse, and perineal hernia) is still high (82%).[36] As an alternative, high-dose radiotherapy has been reported to be an effective form of treatment for distal rectal adenocarcinomas that can be completely prolapsed through the anal opening. Polyps and carcinoma in situ are generally easily excised or treated with cryosurgery or electrocautery, with good to excellent postsurgical results and few recurrences.[29,34] Preliminary work suggests that treatment of dogs with rectal tubulopapillary polyps using piroxicam is also effective.[40]

224.4.2.4 Prognosis

The prognosis for rectal polyps, carcinoma in situ, leiomyoma, and fibroma is generally good; postoperative complications are few, and the recurrence rate is low. Adenocarcinoma, lymphosarcoma, and plasmacytomas all tend to recur, and because of their aggressive nature, treatment with surgery or other means may lead to secondary complications.[29] Annular colorectal adenocarcinoma is a particularly aggressive tumor and is often associated with a very poor prognosis (e.g., mean survival of 1 to 2 months)

because of the complications of treatment, secondary effects (e.g., constipation), and recurrence (e.g., due to difficulty in removing all of the tumor).[29,39]

224.4.3 Rectal Prolapse

Rectal prolapse is defined as eversion or prolapse of the rectum through the anal opening. A prolapse can be partial or complete; a *partial prolapse* involves a protrusion of the rectal mucosa, whereas a *complete prolapse* involves the entire rectum and may include part of the anus as well.

224.4.3.1 History and Physical Examination

Rectal prolapse shows no breed, age, or gender predisposition in dogs or cats. However, it is more prevalent in young animals with typhilitis or proctitis secondary to endoparasites.[1] Manx cats with neurologic dysfunction of the anorectum also appear to have a higher predilection for the condition.[19] Other factors that increase tenesmus and are associated with an increased risk of rectal prolapse include rectal polyps or neoplasia, rectal deviation, dystocia, urolithiasis, prostatic disease, and colonic or rectal foreign bodies.[1,19,41] Rectal prolapse has also been reported as a sequela of perineal urethrostomy in the cat.[42] The diagnosis is made by finding the everted, edematous, and hyperemic prolapsed rectal tissue. In longstanding cases of rectal prolapse, the tissues may be ulcerated and necrotic. A complete rectal prolapse typically appears as a cylindrical mass with a depression at the end, which represents the bowel lumen. The mass usually is sensitive or painful to the touch (Figure 224-4).

1413 1414

224.4.3.2 Diagnosis

Although a diagnosis of rectal prolapse is made by finding the everted rectal tissue on physical examination, the condition must be distinguished from a small or large intestinal intussusception, which can cause similar presenting signs and can have a similar physical appearance. The easiest way to differentiate the two is to pass a well-lubricated, blunt probe between the rectal wall and the prolapsed tissue. With a rectal prolapse, the probe cannot pass between the tissues because the everted rectal tissue converges with the mucocutaneous junction of the anus.[1,14] Intussusception is also typically associated with signs of intestinal obstruction (e.g., vomiting, anorexia), whereas a rectal prolapse is not associated with systemic signs. Anal prolapse must also be distinguished from rectal prolapse; however, in most cases anal prolapse is not associated with a large amount of protruding mucosa and may appear to worsen after defecation. Most cases of anal prolapse are self-limiting and temporary, and the condition frequently occurs secondary to repair of a perianal hernia.

Figure 224-4 Complete rectal prolapse in a cat with colorectal adenocarcinoma and severe tenesmus.

224.4.3.3 Pathogenesis

Dyschezia and tenesmus are common signs of rectoanal disease, yet concurrent development of rectal prolapse is uncommon. This suggests that an individual predisposition probably contributes to the development of a prolapse; such predispositions may include weakness of the perirectal and perianal connective tissues or musculature or uncoordinated peristaltic contractions of the rectum in association with rectal or anal inflammation.[1,43] However, no carefully conducted studies have been done that further evaluate these possible connections.

224.4.3.4 Therapy

The first goal of treatment is to identify and eliminate, if possible, any underlying causes of the prolapse. If the prolapsed tissue is healthy and the amount of exposed mucosa is minimal, a conservative treatment approach can be used. This technique involves rehydrating the tissue with a warm isotonic saline solution, followed by application of a watersoluble gel lubricant, gentle massage and manipulation to reduce edema, and gentle but immediate attempts to reduce the prolapsed tissue. If this regimen is successful, a loose purse-string perianal suture (enough to allow passage of soft feces) is placed to prevent recurrence. Postoperative straining can be prevented by administration of a narcotic epidural or topical anesthetic drops. Adjunctive therapy includes feeding a highly digestible diet and administration of a stool softener or laxative for 2 to 3 weeks. The purse-string suture can be removed in 2 to 3 weeks, once the underlying problem has been corrected.

If conservative therapy fails, a colopexy procedure, to fix the rectum and colon in place, is indicated.[43,44] This procedure places a slight amount of cranial traction on the descending colon, because four to six nonabsorbable mattress sutures are placed in the descending colon, which is attached to the left abdominal wall. If the rectal or colonic tissue is devitalized, lacerated, or irreducible, it must be amputated in conjunction with a full-thickness anastomosis of the remaining rectal segments.[43,44] Postoperative management of these animals is the same as the conservative management of rectal prolapse: a purse-string suture is placed to reduce the possibility of recurrence, a low-residue diet is fed to reduce stool volume, and stool softeners are given for 2 to 3 weeks to keep feces soft and able to pass through the purse-string opening.

224.4.3.5 Prognosis

The prognosis for the first rectal prolapse episode or for animals with a partial prolapse is generally good. Animals with a complete prolapse or recurrence after conservative therapy often require a colopexy and have a guarded to good long-term prognosis. The prognosis for patients that require amputation of the prolapsed tissue is more guarded because of the technical demands of the surgery, the great potential for leakage and infection during the postoperative period, and the increased risk of development of a rectal stricture.[14,43]

224.4.4 Rectal or Anal Stricture

Rectal or anal strictures cause narrowing of the lumen due to scar tissue that forms as a result of rectal inflammation, rectal trauma (from injury or surgery), or proliferative neoplastic disease in the rectum. The clinical picture (e.g., constipation, dyschezia, and, ultimately, vomiting or anorexia) is indistinguishable from that presented by extraluminal narrowing of the colon due to neoplasia, prostatic disease, or pelvic fracture.

1414
1415

224.4.4.1 History and Physical Examination

The typical history is an older dog that has chronic constipation or progressively more difficulty defecating. Affected dogs have persistent tenesmus, prolonged posturing to defecate, and frequent attempts to defecate, with only a narrow ribbon of feces or no feces produced.[14] If concurrent colorectal inflammatory or neoplastic disease is present, hematochezia, mucoid feces, or diarrhea may be observed. As the duration

and severity of the obstruction worsen, other systemic signs may be observed (e.g., lethargy, anorexia, vomiting, weight loss). Several conditions can predispose dogs to the development of a rectal stricture, including recent rectal or anal surgery, chronic rectal or anal inflammation, rectal neoplasia, and ingestion of foreign material that causes rectal trauma as it is passed.

Digital rectal examination is sufficient to identify a narrow and often very tight rectal or anal opening (Figure 224-5). Benign strictures are firm, thick, annular fibrotic bands that must be differentiated from neoplastic strictures, which tend to be asymmetric, masslike formations. However, annular rectal adenocarcinoma cannot be distinguished from a benign fibrotic stricture by palpation alone. The only other physical abnormality found in dogs with rectal stricture is an enlarged colon with hard or impacted feces.

224.4.4.2 Diagnosis

In most dogs, the history and physical examination are sufficient to identify a stricture. The key aspect of diagnosis is determining whether the stricture is malignant or benign. Radiographs and ultrasound scans of the abdomen and pelvis are important, because they rule out other causes of constipation/obstipation, such as pelvic fractures, prostatomegaly, and abdominal masses that affect the colon or sublumbar lymphadenopathy. Contrast radiography is not usually necessary to make a diagnosis of stricture, but it may be helpful for determining the extent of the stricture if the opening is too narrow for physical analysis. Rectal probe ultrasonography can be used to determine the extent of rectal involvement or to detect other lesions. Ultimately, however, biopsy is necessary to determine whether the lesion is benign or malignant. Biopsy of tissue can be obtained through rigid proctoscopy, flexible endoscopy, or direct visualization by prolapse of the affected rectal tissues. A major limitation on the use of either a rigid or a flexible scope to obtain biopsy specimens is that passage of the scope and distention of the rectum (for visualization) often is impossible. In such cases, direct prolapse or surgical biopsies must be obtained.

Figure 224-5 Severe rectal stricture identified on digital rectal examination.

224.4.4.3 Therapy

Previously, rectal strictures were managed by surgical techniques, such as rectal pull-through or rectal myotomy procedures.[14] More recently, bougienage and balloon dilatation techniques have gained favor, because when performed properly, they are often successful in dilating the stricture site without incurring the severe complications that frequently accompany surgical correction (e.g., fecal incontinence, infection, dehiscence, or restricture).[14] To facilitate appropriate visualization and comfort for these procedures, the dog or cat should be anesthetized, and if possible the procedure should be done with endoscopic or fluoroscopic assistance.

For bougienage of rectal strictures, a metal bougie of increasing size (over several separate but successive procedures) is passed into the stricture site and advanced slowly, stretching the fibrous tissue without causing significant tearing, which tends to increase inflammation and the likelihood of restricture.

Like esophageal strictures, rectal strictures also can be successfully dilated using balloon dilatation techniques, and this approach is frequently preferred over bougienage. The diameter of the balloon and the number of dilatations required to achieve a sustained opening in the rectal lumen are quite variable, but chronic strictures in larger animals may require several procedures to achieve functional success. In general, for small dogs (less than 7 kg) and cats, balloons with a diameter of 10 to 15 mm are used; for medium-sized dogs, the balloon diameter is 20 to 30 mm; and for large dogs (greater than 16 kg), it is 30 to 40 mm.[14] These numbers are guidelines, because animals with severe rectal strictures may require much smaller balloons for the initial procedure to prevent excessive tissue tearing. In dogs with recent strictures or those without excessive fibrosis, one or two dilatation procedures 4 to 5 days apart may be all that is required to dilate the affected tissue successfully. However, when rectal wall thickening is present or the reduction in the lumen is greater than 75%, four to six dilatation procedures may be required to achieve functional success.[14] The purpose of performing multiple procedures several days apart (but no more than 7 days) is to increase the diameter of the stricture waist gradually, without excessive tearing or inflammation; this gradual approach reduces the likelihood of restricture (which tends to occur in 7 to 10 days).[14] Careful visualization of the procedure ensures that tearing and hemorrhage are kept to a minimum and reduces the risk of deep tears or significant hemorrhage, which increase the likelihood of restricture or rectal perforation. Adjunct therapy should include administration of broad-spectrum antibiotics, a highly digestible (low-residue) diet, and use of lactulose or stool softeners to maintain a soft fecal consistency. The use of corticosteroids to reduce the occurrence of restricture has not been studied, and such therapy should be undertaken cautiously if rectal tears or bacterial contamination is suspected.

224.4.4.4 Prognosis

For most benign rectal strictures, the prognosis is guarded to fair, because balloon procedures may allow return to near normal functionality; however, unless the predisposing cause of the stricture is corrected, it is likely to recur. The risk of severe complications after balloon procedures is lower than for surgical repair techniques, primarily because the risk of inducing fecal incontinence is greatly diminished. The prognosis for all neoplastic strictures is poor, owing both to the difficulty in managing the primary problem and to the poor response to balloon or other management techniques.

224.5 DISEASES OF THE ANUS

224.5.1 Atresia Ani

Atresia ani, a congenital condition that affects the anal opening and rectum, may occur in both puppies and kittens. The several anatomic variations of atresia ani have been classified as types I through IV, but all generally result in an abnormal anal outlet and/or rerouting of feces from the rectum to another outlet.[14,45] Pets with type I, or imperforate anus, have a membrane over the anal opening, but the rectum ends as a blind pouch just cranial to the anal opening. Type II is similar to type I, but the rectal pouch ends much more cranial to the anal opening. In type III, or rectal atresia, the rectum ends in a blind pouch in the abdomen (cranial to the pelvis), and the remaining rectum and anus are normal. Type IV, which occurs only in females and may occur with or without imperforate anus, is characterized by a persistent communication between the rectum and vagina (rectovaginal fistula) or urethra (rectourethral fistula).[45]

224.5.1.1 History and Physical Examination

The clinical signs are often noticed at weaning (4 to 6 weeks) or earlier in affected puppies and kittens. In general, types I, II, and III create similar problems: straining to defecate, bulging of the perineum, absence of feces, no visible anal opening, abdominal distention with palpable fecal material, and abdominal or perineal discomfort.[14] Initially, the puppy or kitten eats and appears to grow, but with increasing fecal distention of the colon, lethargy or restlessness, loss of appetite, and vomiting are noted. Type IV often is associated with tenesmus but is characterized by the passage of small amounts of watery feces via the vagina or urethra, with associated perivulvar erythema and infection.

224.5.1.2 Diagnosis

The diagnosis is based on finding the typical physical abnormalities in a puppy or kitten of appropriate age that has a concurrent history of tenesmus or lack of ability to defecate normally. For type I or II atresia ani, absence of an anal opening is diagnostic. In type III, radiography or ultrasonography may be helpful for defining the end of the rectal pouch. In type IV, the presence of fecal material exiting through the vaginal opening is suggestive.

Another congenital anomaly that may occur in dogs and cats and that can be confused with atresia ani is anogenital cleft. This condition occurs in females and is characterized by continuity of the mucosa of the anus, rectum, and vagina along the perineal midline.[45] A similar anomaly can occur in male cats resulting from a rectourethral cleft, which is a communication that allows a common opening for the rectum and urethra.

224.5.1.3 Therapy

The only treatment available is surgical correction, which may require staged procedures, depending on the type of anomaly present. Type I atresia ani is the simplest to correct, because opening of the anus and ballooning of the stricture may be all that is required in some animals. In animals for which this procedure is unsuccessful, the stenotic segment often must be surgically removed. Types II and III require significant and technically demanding surgical procedures to return functionality. In all three circumstances, fecal

incontinence is a major and often life-threatening complication. Type IV lesions require technically demanding surgery to close the rectal, vaginal, and urethral defects.

224.5.1.4 Prognosis

Regardless of the anomaly, young and weak puppies or kittens often do not survive the procedure. In addition, the prognosis is guarded to poor for complete return of normal anal or rectal function for any type of atresia ani. This is primarily because of the likelihood of injury to the external anal sphincter or its innervation during surgical repair. Another common surgical complication of this procedure is the development of rectal or anal strictures. Also, many affected puppies and kittens have concurrent megacolon, which develops as a result of persistent fecal impaction and which may be irreversible, requiring indefinite aggressive medical management or a subtotal colectomy.

224.5.2 Perianal Fistula

Perianal fistula is a chronic, often debilitating disease of the perianal tissues in dogs characterized by one or, more often, multiple draining tracts surrounding the anus. Anal furunculosis, an alternate descriptor, is typically a progressive disease characterized by ulcerative, painful, malodorous lesions resulting from the associated tissue destruction and infection. In severe cases, the entire anus is surrounded with ulcerative, draining tracts that often lead to fecal incontinence or rectal stricture formation (Figure 224-6). The fistulas usually do not involve the anorectal canal directly; however, typical signs include self-mutilation, dyschezia, and rectal stenosis, resulting in fecal incontinence or constipation.

224.5.2.1 History and Physical Examination

Perianal fistulas occur primarily in older, large breed dogs with a broad-based tail and lower tail carriage, which may create an environment that predisposes these breeds to perianal problems. The two breeds with the highest incidence of perianal fistula are German shepherds and Irish setters, but sheepdogs, retrievers, and spaniels also may develop the disorder.[46–49] No distinct gender or age predilection appears to exist, but the condition is more prevalent in male dogs over 5 years of age.[46,49] Because of the animal's low tail carriage, the disease may not be noticed by the owners until obvious lesions are present or the discharge or odor becomes overpowering. The only abnormality reported by some owners, especially early in the course of the disease, is persistent licking of the anus. Other clinical signs that may be reported include hematochezia, dyschezia, perianal discharge, constipation, and tenesmus. In severely affected dogs, anorexia, weight loss, and behavioral changes may occur as a result of the discomfort.

Physical examination may be difficult, if not impossible, without sedation because the simple act of having the tail lifted is painful to the animal. The examiner may also need to clip the hair and cleanse the area to fully assess the extent of the perianal involvement. Visual inspection reveals multiple, ulcerated, draining tracts that extend into the tissues surrounding the anus. The lesions are often extremely malodorous and, in outdoor dogs, may contain fly maggots. Rectal strictures, abnormal anal tone, or granulomatous rectal mucosa may be found during a digital rectal examination. In addition, in some dogs with perianal fistulas, the anal sacs are involved in the fistulation, which may result in anal sac obstruction or abscessation.

Figure 224-6 Severe fistulating and ulcerative perianal fistula in a German shepherd.

224.5.2.2 Diagnosis

A diagnosis of perianal fistula is usually made based on the combination of typical signalment and history and physical examination findings. Important differentials for this condition include chronic anal sac abscessation with secondary fistulas, aggressive perianal tumors (e.g., adenocarcinoma), caustic injury, and untreated dog bite wounds.[14] A digital rectal examination and probing of the extent of the lesions while the dog is under general anesthesia confirms the diagnosis. Because German shepherds are predisposed to this condition and often have other concurrent colonic or rectal abnormalities, a proctoscopic or colonoscopic examination is also recommended.[48]

224.5.2.3 Pathogenesis

The factor long considered to be the most important contributor to formation of perianal fistulas is anatomic predisposition,[47] including (1) a broad-based tail (e.g., German shepherds), (2) low tail carriage (e.g., Irish setters), and (3) increased density of apocrine sweat glands in the zona cutanea.[47,49] More recently, an immune-mediated basis for the disease has been suggested by clinical trials, which have demonstrated a positive response to prednisone therapy in affected German shepherds.[48] This proposed etiology is further supported by the positive response to treatment seen in clinical trials using azathioprine, cyclosporine, and tacrolimus.[50–54] In humans, food allergy is believed to be a component of the development of perianal fistulas; although this has not been proved in dogs, it may also be a contributing factor in this species. The development and pathogenesis of perianal fistulas likely constitute a multistage process, in which an inflammatory condition sets the stage (e.g., immune-mediated, allergic, or anatomic causes) and is followed

by the development of a secondary bacterial infection that results in severe epidermal ulceration and necrosis.

224.5.2.4 Therapy

The two basic approaches that have been used in the management of perianal fistulas are medical management and surgical excision. In many cases, medical management alone is sufficient for control; however, in severe cases, a combination of medical and surgical treatment often is necessary. Recently, laser surgical excision has met with some success in a limited number of cases; however, as with surgical approaches, fecal incontinence is a potential complication.[19,37,55]

Medical management of perianal fistulas has four components: (1) removal of perineal hair and tissue cleansing, (2) immunosuppressive therapy, (3) antibacterial therapy, and (4) dietary therapy.[19] In one study, a combination of high-dose prednisone (2.2 mg/kg PO2) and dietary therapy using novel antigen diets resulted in complete resolution of signs in one third of the dogs, improvement in another third, and no change in the remaining one third.[48] More recently, immunosuppressive therapy with azathioprine (50 mg/kg every 24 hours PO) or cyclosporine (1 mg/kg every 12 hours PO) has proved effective in controlling (90% had complete resolution within 2 weeks, 50% had no recurrence in 12 months) or reducing disease, whether used alone or in combination with surgical therapy.[50,51,53,54] In another study, the addition of ketoconazole to cyclosporine therapy proved helpful by allowing a dramatic reduction in the cyclosporine dose (by 80% to 90% in all dogs).[50,54] In most dogs, antibacterial therapy with a first-generation cephalosporin is used to control bacteria typically associated with infections of the skin (e.g., staphylococci). The use of novel antigen diets in the management of perianal fistulas in dogs has not been evaluated in a controlled setting, therefore the effectiveness of this aspect of therapy is unknown; however, in one study the use of these diets was helpful.[48]

For dogs with severe perianal fistulas or those who do not respond to medical management alone, surgical or laser surgical excision of the affected tissue is recommended. A variety of surgical procedures may be necessary, including deroofing (removing the skin covering the fistulous tract) followed by electrofulguration (or electrocoagulation), anal sacculectomy, excision or debridement of diseased tissue, rectal pull-through procedures when rectal strictures are involved and, in some cases, tail amputation.[46,49,55] Carbon dioxide (CO_2) laser therapy may be a very effective means of debridement for dogs requiring surgical therapy, because the laser reduces bleeding, pain and postsurgical swelling.[37]

224.5.2.5 Prognosis

The overall prognosis is guarded in dogs with a perianal fistula, even though most methods, whether medical or surgical, have met with some degree of success. The most common complications of surgical approaches are fecal incontinence, rectal stricture, and recurrence. Therefore medical therapy with prednisone and cyclosporine should be used as the first-line approach in the majority of dogs, with surgical palliation kept a last resort.

224.6 DISEASES OF THE ANAL SACS

224.6.1 Impaction, Anal Sacculitis, and Abscessation

Several common infectious or inflammatory diseases affect the anal sacs, including anal sac impaction, anal sacculitis, and abscessation of the anal sacs. These diseases are more common in dogs than cats, affecting up to 12% of the canine population.[56]

224.6.1.1 History and Physical Examination

The most common clinical signs of anal sac disease are anal pruritus or pain, which elicits licking or biting at the tail or anal region, "tail chasing" behavior, scooting or rubbing of the anus on the ground, and reluctance to sit or discomfort when sitting.[14,57] In more severely affected dogs, pain may cause dyschezia, tenesmus, or reluctance to defecate. Dogs with longstanding anal sac disease may develop large swellings in the area over the anal sac, and if the abscessed sac ruptures, a draining fistula will extend from the affected anal sac.

External or internal digital palpation of the anal sacs may be required in some cases to detect diseased or impacted anal sacs. Normal anal sac secretions are liquid, brown, and foul smelling but easily expressed from the sac through the ducts to their openings on the anus.[57,58] In dogs with anal sac impaction, the material often becomes pasty or even dried and may be difficult to express without causing the animal pain. The material present in infected or abscessed anal sacs is often thicker, may be purulent or bloody, and frequently is very malodorous.

224.6.1.2 Diagnosis

In most pets the history of anal pruritus, along with visual inspection of a perianal swelling at either the 4 to 5 o'clock or the 7 to 8 o'clock position lateral to the anus, is highly suggestive. In the absence of significant visible external swelling, a digital rectal examination is sufficient to confirm anal sac involvement. Some dogs and all cats require sedation for safe performance of a rectal examination because of the accompanying discomfort. Impaction of the anal sacs is confirmed by removal of thick, pasty anal sac material or by inability to empty the sacs easily with appropriate technique. If the anal sacs are painful when gently palpated or if the material expressed is purulent or a color other than light tan to brown, anal sacculitis should be suspected. If doubt exists, a sample of the material can be cytologically examined for large numbers of neutrophils, bacteria, or yeast (e.g., *Malassezia* sp.).[58] If the anal sac is infected or abscessed, fever may also be present. The major differentials in dogs and cats with these clinical signs are perianal fistulas, perianal or anal tumors, and bite wounds (cats) or other trauma.

1417 1418

224.6.1.3 Pathogenesis

The most common cause of inflammation or infection of the anal sac is obstruction of the ducts, which prevents normal (frequent) expulsion of the material and allows bacteria normally present (e.g., *Escherichia coli, Streptococcus faecalis,* and *Clostridium* spp.) to set up a secondary infection.[58] Anatomic conformation also may play an important role in the tendency to develop anal sacculitis or abscessation; for example, smaller than normal ducts or aberrant duct placement on the anus decreases effective emptying.

Other contributing factors may be dogs that produce thicker secretions, the development of abnormal anal tone, the production of soft feces, and recent estrus in females.[57,59]

224.6.1.4 Therapy

Treatment of simple anal sac impaction is straightforward, requiring that the anal sacs be emptied by gentle digital manipulation. If the sacs cannot be easily or completely emptied, they should be gently flushed with warm saline or mineral oil to loosen the concretions and pasty material. Once the sacs are empty, an antibiotic and steroid ointment or solution can be instilled to reduce local infection and inflammation. The sacs should be kept empty for several weeks to prevent recurrence or possible abscessation. In dogs with chronic impaction, the owners can be taught to express the anal sacs at home or, as an alternative, the anal sacs can be surgically removed.

Dogs with anal sacculitis or abscessed anal sacs must also have the sacs emptied, but because of the associated discomfort, sedation or anesthesia is usually required. In dogs with anal sacculitis alone, the sacs should be gently flushed with an antiseptic solution (e.g., dilute [0.5%] chlorhexidine) and antibiotic solution instilled into the sacs. Broad-spectrum oral antibiotic therapy is recommended for 10 to 14 days, along with application of hot compresses to reduce swelling and pain and frequent anal sac expression. In most cases managed this way, the infection resolves completely, and further therapy is not necessary. However, for dogs that have frequent recurrence of anal sacculitis, anal sac removal should be considered.[60–62]

Abscessation of the anal sacs is managed as is other abscessed tissue: the abscess must be surgically opened, flushed, and debrided. This procedure should be repeated daily for 2 to 4 days to help keep the area open and draining and to help remove any additional material that forms in the sacs. A broad-spectrum antibiotic should be administered for 10 to 14 days. Application of hot compresses several times daily for 3 to 5 days also helps reduce the swelling and pain. Surgical removal of the abscessed anal sac is not recommended unless there is recurrence after appropriate treatment. In addition, the surgery should not be performed until antibiotic therapy has been administered long enough to ensure tissue healing. Anal sac removal is recommended when all other options fail, primarily because of the risk of complications, especially fecal incontinence. A recent retrospective report revealed that closed anal sacculectomy procedures were 13 times less likely to have postoperative complications compared with open techniques,[60] which makes the closed approach considerably more viable.

224.6.1.5 Prognosis

The prognosis for anal sac impactions and anal sacculitis is generally good, because these cases typically respond completely to conservative medical management. Most dogs and cats with anal sac abscesses also respond well to aggressive medical management of the infection; however, because these conditions may be more difficult to treat or may recur, surgical anal sac removal may be required. The prognosis for animals requiring anal sacculectomy is guarded to good, depending on the technique used and the surgeon's skill. The primary risk postoperatively is the development of fecal incontinence, especially in older dogs that have reduced anal sphincter tone or function.

224.6.2 Anal Sac, Anal, and Perianal Tumors

Tumors of the anus and perianal integument are relatively uncommon in dogs, and their clinical importance can vary widely. These tumors can range from the benign perianal gland adenoma of older intact male dogs to the malignant perianal gland adenocarcinoma that is most common in older intact or spayed female dogs.[63,64] Anal sac adenocarcinomas and perianal gland tumors are reported primarily in dogs, although a Siamese cat with an anal sac adenocarcinoma recently was reported.[65] Other anal and perianal tumors can occur in cats and dogs but are extremely uncommon. These tumors include perianal adenocarcinoma, squamous cell carcinoma, and melanoma.[64] Large breed dogs, especially German shepherds and Alaskan huskies, appear to be predisposed to the development of perianal adenocarcinomas.[64]

224.6.2.1 History and Physical Examination

The typical history of a dog with an anal sac adenocarcinoma is an older (greater than 10 years) female dog with dyschezia or perineal swelling. However, male dogs are occasionally affected, and the tumor can occur in younger dogs without an identifiable external swelling. This aspect of the disease illustrates the importance of a digital rectal examination as part of a complete physical examination, even in female dogs without clinical signs of tenesmus, dyschezia, or hematochezia. In dogs with paraneoplastic hypercalcemia of malignancy, a common complication of this tumor, the owner may also note polyuria, polydipsia, muscle weakness, or vomiting. Tumors of the anal sac are detected by careful palpation of the anal sac and its associated structures. Most of these tumors are unilateral, and they may be quite small (0.2 to 1 cm), which is why the examination must be performed carefully.[64] With few exceptions, these tumors, regardless of their size, have metastasized to the external iliac (sublumbar) lymph nodes by the time of the examination.[66] Other sites of metastasis include the liver, spleen, abdominal lymph nodes, and lungs. Most hypercalcemic animals become systemically ill, which suggests the need for a complete hematologic and biochemical evaluation; however, all hypercalcemic animals should have a thorough digital rectal examination initially to rule out anal sac adenocarcinoma.

The benign perianal gland tumors (circumanal gland, or hepatoid, adenomas) affect all breeds of dogs, but cocker spaniels, bulldogs, beagles, and Samoyeds appear to be over-represented.[64] Because these tumors develop and grow under the influence of plasma androgens, more than 85% of them are found in older intact male dogs. In most dogs, the tumor is visible in the perianal integument, but it can be found in a variety of sites, including the prepuce, inguinal region, or ventral tail skin.[64] The tumors are usually firm, single, nodular masses of variable size. They can ulcerate, bleed, necrose, or cause intense pruritus of the anal region that may lead to difficulty in defecation, scooting, and other signs of anal disease.

1418 1419

224.6.2.2 Diagnosis and Pathophysiology

Diagnosis of benign perianal tumors is based on the finding of a mass in an intact male dog with the typical signalment and history and physical examination findings. The diagnosis is confirmed by fine needle aspiration cytology or excisional biopsy. The main differences between malignant perianal tumors and their benign counterparts are that the malignant tumors are not influenced by androgens, they behave more like anal sac adenocarcinomas (e.g., have metastasized by the time of diagnosis), and they are difficult to excise completely because of their location, rapid spread, and local infiltration.[64]

A presumptive diagnosis of an anal sac adenocarcinoma, based on the history and physical examination findings and with or without concurrent hypercalcemia, should be followed by histopathologic confirmation. In addition to diagnosis of the tumor, the evaluation should include a thorough systemic examination, including a complete blood count, serum biochemistry profile, urinalysis, and survey radiographs of the chest and abdomen to assess for tumor metastasis and paraneoplastic effects. Abdominal ultrasonography is also frequently used to assess the size and involvement of abdominal lymph nodes or the liver, because metastasis has occurred in greater than 50% of affected dogs by the time of diagnosis.[66] Humoral hypercalcemia of malignancy is present in 50% to 90% of dogs with anal sac adenocarcinoma. The molecular basis for the development of these anomalies is not completely understood, but the tumor results in expression of a gene for parathyroid hormone–related peptide (PTH–rP), which has functions similar to that of naturally occurring parathyroid hormone.[63,64] In some cases, the hypercalcemia may be severe enough to lead to multiple organ dysfunction. After complete removal of the tumor, hypercalcemia may resolve; however, hypercalcemia persists in dogs with metastatic disease or incomplete removal of the anal sac tumor.

224.6.2.3 Therapy and Prognosis

Castration and removal of the primary tumor by surgical excision or cryotherapy constitute the treatment of choice for perianal gland adenomas.[64] It is a more difficult procedure for large tumors and in those cases is more frequently associated with postoperative side effects (e.g., wound dehiscence, fecal incontinence, and hernia). In general, benign perianal gland tumors are slow growing; consequently, they are effectively treated with surgical excision, cryosurgery, electrocautery, and laser surgery, and they rarely recur (rate is less than 10%). The long-term prognosis is excellent except in cases of large tumors that cannot be completely excised.

Malignant perianal tumors are rapid growing, do not regress after castration, and because of their rapid metastasis are often not completely removed by surgical excision. For both perianal and anal sac adenocarcinomas, aggressive surgical removal with adequate margins, along with excision of regional lymph nodes, is recommended.[64] Despite aggressive surgical approaches, a local recurrence rate of 50% is reported for female dogs with adenocarcinoma.[64] Some oncologists suggest combination therapy, comprising surgical removal followed by platinum or doxorubicin chemotherapy to further control metastasis and local recurrence. Intraoperative irradiation of regional lymph nodes has proved successful at stopping metastasis in a limited number of cases.[64]

Nevertheless, the average survival of dogs with anal sac adenocarcinoma is reported to be 8 months (range, 2 to 39 weeks).[60,64] If the tumor is discovered early, before metastasis, and is completely excised, the prognosis is good. The prognosis for smaller tumors is slightly better (e.g., fair) than for those greater than 5 cm, because the surgery is more effective and is associated with fewer complications. With large tumors, tumors with obvious metastasis, or concurrent hypercalcemia, the long-term prognosis is poor (survival rate of less than 40% at 1 year).

224.6.3 Fecal Incontinence

Fecal incontinence is defined as the inability to control defecation and retain feces until voluntary, conscious defecation is initiated.[14] Animals with fecal incontinence pass feces involuntarily and are often euthanized

because of the difficult social issues that result. Fecal incontinence can be caused by neurologic disorders that affect function of the anal sphincter, primary disorders of the external anal sphincter (e.g., non-neurogenic sphincter disorders), or diseases that affect the normal reservoir function of the colon or rectum (e.g., reservoir incontinence) (Box 224-2).[14] In general, animals with sphincter incontinence have more severe signs (e.g., lack of conscious posture to defecate, uncontrolled passage of feces) and are likely to be irreversibly affected. Animals with severe inflammatory disease may also have loss of voluntary control of defecation as a result of urgency to defecate, tenesmus, or hematochezia, but the problem may resolve with appropriate treatment of the disease.

224.6.3.1

Box • 224-2 Causes of Fecal Incontinence

224.6.3.1.1

Neurologic Disease

Sacral spinal cord

Congenital vertebral malformation

Meningomyelocele

Sacrococcygeal hypoplasia of Manx cats

Sacral fracture

Sacrococcygeal subluxation

Lumbosacral instability

Viral meningomyelitis

Discospondylitis

Degenerative myelopathy

Neoplasia

Peripheral neuropathy

Trauma

Repair of perineal hernia

Perianal urethrostomy

Penetrating wounds

Dysautonomia

Hypothyroidism

Diabetes mellitus

224.6.3.1.2 Non-Neurologic Disease

Colorectal causes

Inflammatory bowel disease

Neoplasia

Constipation

Anorectal causes

Trauma

Surgery (anal sac, perineal hernia, rectal resection)

Perianal fistula

Neoplasia

Miscellaneous causes

Severe diarrhea

Irritable bowel syndrome

Decreased mentation

Old age

224.6.3.2 History and Physical Examination

Determination of the cause of fecal incontinence requires a careful, complete history. In particular, it is important to distinguish fecal incontinence from urgency to defecate. Furthermore, the mere presence of fecal material accumulating around the anus must be distinguished from lack of ability to control the anal sphincter and fecal dribbling. Examples of diseases or circumstances that may damage nerves or muscles and lead to fecal incontinence include previous spinal cord disease, pelvic trauma, dystocia, chronic constipation, and anorectal surgery.[14] Animals with frequent, conscious defecation associated with normal posturing usually have normal anal sphincter and nerve function but may have incontinence as a result of loss of reservoir function. The most common causes of reservoir dysfunction are inflammatory, infectious, and neoplastic diseases of the colon, rectum, or anus that cause decreased compliance and abnormal motility. Severe large bowel diarrhea secondary to colonic inflammation can cause fecal incontinence for the same reason. In most animals with neurogenic or non-neurogenic sphincter incontinence, the fecal stream is normal. Furthermore, in animals with neurogenic sphincter incontinence, abnormal micturition often occurs concurrently because of the common neural pathways.[4] The urinary abnormalities may include dribbling urine, incomplete voiding, or inability to void, and when these occur in conjunction with fecal incontinence, neurologic dysfunction should be strongly considered.

The physical examination should include careful inspection of the perineum for evidence of abscesses, fistulas, hernias, masses, or other abnormalities. After the visual inspection, a digital rectal examination is performed to assess for normal anal sphincter tone, fecal impaction, strictures, or masses. Abdominal palpation is necessary to determine the presence of colonic impaction, as well as bladder size and expressibility. A distended, flaccid bladder from which urine is easily expressed is consistent with a lesion of the sacral spinal cord, the sacral nerves, or the pudendal nerve.[4] A complete neurologic examination, including observation of gait and posture, evaluation of myotactic and postural responses, and assessment of lumbosacral pain, is required in any animal suspected of having fecal incontinence. The neurologic deficits that may be present in dogs with neurogenic sphincter incontinence are abnormal posture, hindlimb gait abnormalities, decreased myotactic reflexes, or an abnormal pudendal (anal) reflex.[67] The anal reflex, which is a measure of perianal sensation and sacral spinal cord function (via the pudendal nerve), is tested by pinching the perianal skin, which results in an immediate contraction of the anal sphincter. This reflex should be present on both the right and left sides of the anus. The pudendal-anal reflex (bulbocavernosus reflex) is tested by squeezing the penis or vulva while observing for normal anal contraction. Lesions of the perineal afferent nerves, the sacral spinal cord, or the pudendal efferent nerves can decrease or abolish these reflexes and cause a dilated anus, loss of perineal sensation, and a loss of micturition control.[67]

224.6.3.3 Diagnosis

When loss of colorectal reservoir function is suspected, the diagnostic plan should include an examination of the fecal stream (e.g., fecal floatation, cytology) and proctoscopy or colonoscopy with biopsy to identify the primary disease. If signs of systemic disease are also detected, further evaluation (e.g., hematology, serum chemistries, radiographs, ultrasonography) is warranted as indicated. Sphincter incontinence (either neurogenic or non-neurogenic) is usually apparent from the history and physical examination. Neurogenic and non-neurogenic dysfunction are differentiated by neurologic examination. If further confirmation is necessary, anal sphincter electromyography or monometry is used to prove sphincter incompetence; however, this is rarely necessary and not universally available. When lesions of the lumbar spinal cord or the cauda equina are suspected, vertebral radiographs, myelography, computed tomography, magnetic resonance imaging, or cerebral spinal fluid analysis may be indicated.[67] The causes of fecal incontinence are listed in Box 224-2.

224.6.3.4 Pathophysiology

Control of fecal continence is maintained by the muscles of internal and external anal sphincters, the rectum, and the coccygeus and levator ani muscles of the pelvis, which are innervated by the pelvic, hypogastric, pudendal, and sacral nerves.[4,67] Both motor and sensory impulses are integrated into the sacral spinal cord to coordinate normal fecal continence. The non-neurogenic causes of sphincter incontinence are usually due to reservoir incontinence (e.g., colitis, neoplasia) or to trauma to the anorectal muscles (e.g., surgery, hernia, fistula, neoplasia) (see Box 224-2).[14]

224.6.3.5 Therapy and Prognosis

The treatment of fecal incontinence depends entirely on the primary cause; for example, loss of reservoir function due to colitis often resolves completely with appropriate treatment, whereas loss of neurologic function is permanent and rarely treatable. Some forms of non-neurogenic incontinence are transient (e.g.,

postoperative complication, trauma), and some forms of neurogenic incontinence may improve after specific treatment (e.g., spinal surgery to reduce compression or subluxation). However, in these cases no specific drugs or diets are particularly effective. Highly digestible diets may be beneficial, because they reduce the volume of fecal material. Enemas and exercise may stimulate defecation at desired times and can be used to help control the social unacceptability of the problem.[68] A surgical technique using an implanted Silastic sling, and placement of an autogenous muscle graft to augment the muscles of continence, have been described, but the success rates for these procedures are not satisfactory.[69] Recently, a technique to create a new sphincter using muscle transplants has shown promise for providing a functional stomal sphincter in dogs with chronic fecal incontinence.[70] Nevertheless, in many pets euthanasia is chosen because in most cases the prognosis is poor for return to normal or acceptable sphincter function.

225 CHAPTER • 225 History, Clinical Signs, and Physical Findings in Hepatobiliary Disease

Cynthia R.L. Webster

The liver plays a central role in a diverse array of processes including carbohydrate, lipid, and protein metabolism; detoxification of metabolites and xenobiotics; storage of vitamins, trace metals, fat and glycogen; fat digestion; and immunoregulation. The clinical signs, physical findings, and clinicopathologic abnormalities that accompany hepatic disease reflect deficiencies in these varied functions. The liver, however, has a tremendous reserve capacity to perform these functions. Thus the appearance of relatively specific signs of hepatobiliary disease such as icterus, hypoglycemia, bleeding tendencies, hepatic encephalopathy (HE), or ascites, which reflect exhaustion of the liver's functional reserves, occur only late in disease progression. Early clinical signs of hepatic disease, such as intermittent anorexia, polyuria/polydipsia (PU/PD), vomiting, and lethargy, mimic those seen with disease in other organ systems. In most cases, early detection of hepatobiliary disease relies on clinicopathologic evaluation and histopathologic examination of hepatic tissue.[1]

Although most early signs of liver disease are nonspecific, several clues should raise one's awareness as to the presence of hepatobiliary disease; these include strong breed predispositions and the occurrence of several clinical recognizable syndromes that accompany hepatobiliary disease, including gastrointestinal (GI) ulceration, HE, tissue jaundice, coagulopathies, and ascites.

Several breed predispositions occur in hepatobiliary disease. Congenital portosystemic vascular anomalies (PSVASs) are most frequent in purebred dogs particularly Irish wolfhounds, Australian cattle dogs, Maltese terriers, Cairn terriers, miniature schnauzers, Yorkshire terriers, dachshunds, Labrador retrievers, and golden retrievers. Feline PSVASs occur most often in mixed breed cats, but Persians and Himalayans are over-represented. Bedlington terriers have a congenital abnormality in hepatic copper metabolism that results in hepatic copper overload and subsequent development of chronic inflammatory hepatobiliary disease. Less well-defined copper-associated hepatopathies occur in West Highland white terriers, dalmatians, Skye terriers, and Siamese cats. Several breeds have a predisposition to develop idiopathic chronic inflammatory hepatobiliary disease, including Doberman pinschers, American and English cocker spaniels, standard poodles, and Labrador retrievers. Hepatic amyloidosis occurs in Chinese Shar Pei dogs and in Abyssinian, Oriental, and Siamese cats.

Historical findings that suggest the presence of hepatobiliary disease include recent ingestion of a known hepatotoxic substance or treatment with a potentially hepatotoxic drug.[2] Stunted growth or anesthesia or drug intolerance (or a combination of these factors) in a young animal, particularly in a predisposed breed, suggests the presence of PSVASs. A recently stressed obese cat that becomes anorexic is a classic historical example of a cat with idiopathic hepatic lipidosis.

The clinical signs associated with hepatobiliary disease are typically referable to the GI, renal, neurologic, or hematopoietic systems (Table 225-1). In addition, a rare dermatologic syndrome called *superficial necrolytic dermatitis* marked by ulcerative crusting dermatitis of the face and distal extremities, accompanies a unique form of chronic liver disease in the dog (hepatocutaneous syndrome).

Intermittent GI signs such as diarrhea, anorexia, and vomiting, are common signs of hepatobiliary disease. Chronic hepatic disease predisposes dogs to gastroduodenal ulceration, so a myriad of clinical signs referable to ulcer disease, such as hematemesis, abdominal pain, and melena, should prompt consideration of an underlying hepatopathy.

HE is neurologic condition associated with failure of the liver to detoxify inhibitory neurotoxins generated in the intestinal tract. The clinical signs are those of diffuse cerebral disease. HE is most often seen with PSVASs or with hepatopathies associated with acquired portosystemic shunts, but may also accompany acute fulminant hepatic failure. In acute failure the neurologic signs of HE can be confused with those associated with hypoglycemia. Either or both problems commonly accompany severe acute hepatic failure. Cerebral edema, an ominous consequence of fulminant hepatic failure, can also cause neurologic signs mimicking HE. These signs include disorientation, stupor, and coma.

An important differential for the presence of abdominal fluid accumulation is hepatobiliary disease. Chronic liver disease, particularly in the dog, can be associated with the development of ascites secondary to the presence of portal hypertension. Portal hypertension develops either due to capillarization of the hepatic sinusoidal endothelium from fibrosis, increased hepatic blood flow such as occurs with arteriovenous fistula, or is secondary to disease or obstruction of the portal vein or its tributaries. Ascites may accompany primary or metastatic hepatobiliary disease or can signal the presence of bile peritonitis from rupture of the biliary tract.

A highly variable, but often predominant, early clinical sign in many dogs and cats with chronic hepatobiliary disease or PSVASs is the presence of polyuria, polydipsia, or both. The mechanism for the polyuria and polydipsia is unknown, but the following six have been hypothesized[3]: (1) psychogenic polydipsia, (2) alterations in portal vein osmoreceptors, (3) decreased hepatic urea production resulting in disruption of the renal medullary concentration gradient, (4) potassium depletion, (5) stimulation of thirst centers due to HE, and (6) increased endogenous cortisol levels associated with increased adrenal production or decreased hepatic degradation.

Animals with hepatobiliary disease may also have signs referable to ammonium biurate urolithiasis such as stranguria, pollakiuria, or hematuria. Ammonia biurate stones form secondary due to chronic hyperammonemia and decreased hepatic processing of uric acid.

The most significant physical finding that should prompt a consideration of hepatobiliary disease is icterus, a yellow discoloration of the mucous membrane associated with accumulation of bilirubin. Pale mucous membranes, abdominal enlargement due to ascites or hepatomegaly, and poor body condition score might be other findings on physical examination of dogs or cats with hepatobiliary disease.

1422 1424

Table • 225-1 Pathophysiology of Common Clinical Signs and Physical Examination Findings in Hepatobiliary Disease

CLINICAL SIGNS	PATHOPHYSIOLOGY	PHYSICAL FINDINGS	PATHOPHYSIOLOGY
Gastrointestinal (GI)		Icterus	Decreased uptake, conjugation or export of bilirubin into bile
Vomiting	Direct stimulation of CRTZ	Hepatomegaly	Hepatic infiltration with inflammatory cells, neoplasia, amyloid, fat, glycogen
	Gastroduodenal ulceration		
	Concurrent intestinal inflammatory disease		
Diarrhea	Concurrent intestinal inflammatory disease	Abdominal fluid	Ascites:
	Steatorrhea		Portal hypertension Avid renal sodium and water retention
	Portal hypertensive enteropathy		Hypoalbuminemia
			Bile: rupture gallbladder/biliary tract
			Neoplastic effusion
Acholic feces	Extrahepatic bile duct obstruction	Poor body condition score	Poor appetite
			Increased metabolic rate
			GI malabsorption
Melena	Gastroduodenal ulceration	Abdominal pain	Cholecystitis
	Coagulopathy		GI ulceration
			Bile peritonitis
			Pancreatitis
Neurologic		Fever	Leptospirosis
			Rickettsial disease
Personality change	Hepatic encephalopathy (HE)		Protozoal disease: *Toxoplasma*,*Neospora*
Weakness	Hypoglycemia		
Anorexia, lethargy	Cerebral edema		Feline Infectious Peritonitis (FIP)
Ptyalism (cats)	Vitamin B1 deficiency		*Salmonella*
Head pressing			Bacterial cholecystitis
Disorientation →stupor → coma			Supporative hepatitis
Irritability/aggression			
Seizures			
Renal			
Polyuria/polydipsia (PU/PD)	Primary polydipsia		
	Decreased hepatic urea production with subsequent disruption renal medullary interstitial gradient		
	Increased circulating cortisol		
	Manifestation of HE		
Pollakiuria, stranguria, dysuria	Ammonium biurate urolithiasis		
Bilirubinuria	Hyperbilirubinemia		
Hematologic	Anemia		

Pale mucous membranes	Blood loss from coagulopathy or GI bleeding Anemia chronic disease

225.1 LABORATORY EVALUATION OF HEPATOBILIARY DISEASE

225.1.1 Clinical Enzymology

Evaluation of serum values of hepatobiliary enzymes such as alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and γ-glutamyl transpeptidase (GGT), are commonly used to screen for the presence of hepatobiliary disease, because consistent increases in the serum concentration of these enzyme activities occur after hepatobiliary injury.[4] Although these serum enzymes have a high sensitivity for the detection of hepatobiliary disease, interpretation of abnormalities is hampered by their lack of specificity for hepatobiliary disease. The central role of the liver in metabolism and its high blood flow make it uniquely sensitive to secondary injury. Thus several clinical conditions exist in which liver enzymes may be elevated but in which clinically significant hepatobiliary disease may not be present (Table 225-2). Although the magnitude of serum enzyme elevation is usually proportional to the severity of active hepatobiliary damage, the degree of elevation is not predictive of hepatobiliary functional capacity. Marked increases in serum enzymes may indicate substantial hepatobiliary injury but, due to tremendous hepatic regenerative capacity, are not necessarily indicative of a poor prognosis. Alternatively, in severe end-stage chronic liver disease, serum enzymes may be normal or only mildly increased, because replacement of hepatocytes by fibrosis, prolonged enzyme leakage, or both has resulted in depletion of total liver enzyme content. A single serum enzyme determination should never be used to establish a prognosis. The prognostic value of serum enzymology is improved by following sequential serum enzyme determinations, especially in conjunction with a hepatic function test or hepatic biopsy.

Alanine aminotransferase (ALT) is a liver-specific cytosolic enzyme. The largest increases in serum ALT, a leakage enzyme, are seen with acute hepatocellular necrosis and inflammation. The magnitude of ALT elevation is roughly proportional to the number of injured hepatocytes. The serum $t_{1/2}$ in dogs is around 2.5 days. No published values exist for feline serum ALT $t_{1/2}$. In acute liver disease in the dog, the finding of a 50% decrease in sequential serum ALT determinations over 2 to 3 days is considered a good prognostic sign. In dogs, serum ALT may also increase with severe muscle necrosis.

In dogs, phenobarbital and corticosteroids increase serum ALT.[4–7] In most dogs, drug induction results in mild increases in ALT (two-to fourfold), but in some individuals increases approach those seen with acute hepatocellular injury. Whether these larger elevations in serum ALT activity represent enzyme induction or are reflective of possible corticosteroid or phenobarbital hepatotoxicity is still unclear. Serum ALT may increase with primary or metastatic hepatic neoplasia.[8] Mild to moderate increases are seen in 70% to 80% of dogs with hepatocellular or bile duct carcinoma. Occasionally hepatic nodular hyperplasia results in increased serum ALT.

Serum AST is more sensitive than serum ALT in the detection of hepatobiliary disease, although considerably less specific because significant amounts of AST are also contained in muscle. The $t_{1/2}$ of serum AST is 5 to 12 hours in the dog and 77 minutes in the cat. In general, increases in serum AST parallel increases in serum ALT and, like ALT, are associated with leakage after altered membrane permeability. In instances where serum AST is much higher than serum ALT, a muscle source for the elevations should be explored. Alternatively, because AST is present within the mitochondria and the cytosol, an elevated AST to ALT ratio

may be indicative of acute severe irreversible injury. In dogs, serum AST is mildly increased by corticosteroids and phenobarbital. Increases in serum AST may be more sensitive than ALP or ALT in the detection of hepatic metastasis.[8]

Table • 225-2 Conditions in which Increases in Serum Hepatobiliary Enzyme Concentrations May Occur in the Absence of Primary Liver Disease

Drug Induction:
Corticosteroids (dogs): (↑↑↑ALP, ↑↑GGT, ↑ALT, ↑AST)
Anticonvulsants: (phenobarbital, phenytoin, primidone) (↑ALT, ↑ALP, ↑AST, ↑GGT)
Endocrinopathies:
Hyperthyroidism (cats): (↑ALP, ↑ALT)
Hypothyroidism (dogs): (↑ALP)
Diabetes mellitus: (↑ALP)
Hyperadrenocorticism (dogs): (↑↑↑ALP, ↑ALT, ↑GGT, ↑AST)
Neoplasia:
Adenocarcinomas: pancreatic, intestinal, adrenocortical, mammary
Sarcomas: hemangiosarcoma, leiomyosarcoma
Hepatic metastasis: (↑AST, ↑ALT, ↑ALP)
Unique enzyme induction: (↑↑ALP, ↑↑GGT)
Miscellaneous:
Systemic infections Pregnancy (cats): (↑placental ALP)
Colostrum fed neonates (dogs):(↑GGT)
Hypoxia/Hypotension: (↑↑ALT, ↑ALP, ↑GGT, ↑AST)
Congestive heart failure (CHF)
Septic shock
Hypoadrenocorticism
Circulatory shock
Severe acute blood loss
Status epilepticus
Hypotensive crisis
Surgery
Muscle Injury: (↑ALT, ↑↑AST)
Acute muscle necrosis/trauma
Malignant hyperthermia
Myopathies
Bone Disorders: (↑ALP)
Young animals (up to 7 months)
Osteosarcoma
Osteomyelitis

Although serum ALP elevation is a sensitive indicator of hepatobiliary disease, its low specificity for liver disease confuses interpretation. ALP's low specificity is associated with the presence of several isoenzymes and a unique sensitivity to drug induction. Isoenzymes of ALP are present in the liver, kidney, intestine, bone, and placenta. The intestinal, kidney, and placental isoenzymes do not contribute to serum ALP due to their short $t_{1/2}$. An exception is in late-term feline pregnancy, where the placental ALP isoenzyme represents a significant source of the serum enzyme. The bone isoenzyme, B-ALP, contributes about one third of total serum ALP.[9] Increased osteoblastic activity associated with growing bones in young animals or with pathologic conditions such as osteomyelitis or osteosarcoma can increase serum B-ALP. These conditions typically cause mild increases in the total serum ALP.

1424
1425

Two liver isoenzymes contribute to the serum ALP in dogs; a liver (L-ALP) and corticosteroid-induced isoenzyme (C-ALP). Cats have only one liver isoenzyme. In the dog and cat, L-ALP is a membrane-bound enzyme found on the hepatocyte canalicular membrane and the luminal surface of biliary epithelial cells.[10] Canine C-ALP is a hyperglycosylated form of the isoenzyme produced by hepatocytes and is also located on the hepatocyte canalicular membrane. The serum $t_{1/2}$ of both L-ALP and C-ALP in the dog is about 70 hours. The $t_{1/2}$ of the cat liver isoenzyme is only 6 hours. Increases in serum ALP in the dog and cat are the result of increased de novo synthesis, elution of the enzyme from cellular membranes, or both.

In a series of 270 dogs with histologically confirmed hepatic disease, the highest serum ALP activities were seen with cholestasis (median: tenfold increase) followed by chronic hepatitis, corticosteroid-induced hepatopathy, and hepatic necrosis (approximately sixfold).[4] Although the specificity of serum ALP determination for hepatobiliary disease was only 51%, the sensitivity was quite high (approximately 80%). Canine bile duct carcinoma and hepatocellular carcinoma can be accompanied by moderate to marked increases in serum ALP (see Table 225-2). Hepatic nodular regeneration, a common hepatic lesion in old dogs is frequently accompanied by mild to moderate increases in ALP.

Exposure of dogs to excess endogenous or exogenous corticosteroids increases serum ALP.[5,6,11] In experimental studies, dogs given immune-modulating doses of prednisone had increases in serum ALP by the third day that continued to rise throughout the period of corticosteroid administration. Serum ALP elevation in corticosteroid-treated dogs is accompanied by changes in hepatic morphology. Morphologic changes include ballooning enlargement of hepatocytes and development of intracytoplasmic hepatic vacuolation due to glycogen accumulation.[6] In some studies, focal areas of hepatocyte necrosis have been described. In dogs treated with prednisone, these morphologic changes begin by the second day and gradually progress in severity as corticosteroid treatment continues.

One of the challenges in the interpretation of canine serum ALP elevations is distinguishing between increases associated with cholestatic hepatic disease and those secondary to exposure to corticosteroids. In theory, serum ALP isoenzyme analysis should separate these two groups, because hepatobiliary disease should increase L-ALP and corticosteroid exposure should increase C-ALP. In reality, considerable overlap exists between isoenzyme distributions in these two conditions. The most widely used technique for serum ALP isoenzyme analysis is levamisole inhibition.[9] This technique is based on the fact that levamisole inhibits L-ALP and B-ALP but not C-ALP. In dogs with normal total serum ALP, C-ALP represents from 5% to 20% of total serum ALP. In experimental dogs treated with corticosteroids, the initial rise in serum ALP is associated with induction of L-ALP, and only after several days of treatment does C-ALP become the prominent isoenzyme. Chronic corticosteroid exposure due to hyperadrenocorticism or iatrogenic hypercortisolism from parenteral, oral, or topical corticosteroid administration, is consistently associated with increases in C-ALP. Serum C-ALP also increases in chronically ill animals, apparently from long-term endogenous cortisol excess. Although highly sensitive for the detection of exposure to corticosteroids, the specificity of isoenzyme analysis is low. Further, many dogs with hepatobiliary disease also have increases in serum C-ALP.[12]

Phenobarbital induces mild (two-to sixfold) increases in serum ALP.[2,7] Phenobarbital may induce either L-ALP, C-ALP, or both.[10] Interpretation of increased serum ALP activity in phenobarbital-treated dogs is complicated by the fact that this drug is a hepatotoxin. Because ALT, AST, and GGT are also mildly induced by anticonvulsants, they may be of no value in differentiating serum ALP increases due to microsomal induction from those associated with morphologic injury. If the serum abnormalities in these enzymes are

greater than two to three times the upper limit of normal, the possibility of phenobarbital-induced hepatotoxicity should be explored. Dogs on chronic anticonvulsant therapy with enzyme induction should have determination of serum albumin, bilirubin, and bile acids to monitor hepatobiliary function.

Because feline ALP is not susceptible to drug induction, elevations in serum ALP are more specific for feline hepatobiliary disease. The magnitude of serum ALP elevations in feline hepatobiliary disease, however, are not as great as those in the dog due to the short $t_{1/2}$ of feline ALP and the fact that hepatic stores of feline ALP are less than in the dog. Thus feline serum ALP is a less sensitive indicator of hepatic disease than in the dog. Clinically, the largest increases in feline ALP are seen in hepatobiliary conditions associated with intrahepatic or extrahepatic cholestasis.

GGT is present in many tissues, although serum GGT concentrations are primarily derived from the liver. Hepatic GGT is located on the hepatocyte canalicular membrane. Serum elevations in GGT are most common with cholestatic disorders and are associated with increased de novo synthesis and membrane elution.

In dogs, moderate to marked increases in GGT are seen with intrahepatic and extrahepatic cholestasis, whereas mild elevations are seen with acute hepatocellular injury. In a series of dogs with histologically confirmed hepatic disease, serum GGT was more specific (87%) than serum ALP (51%) in the detection of hepatobiliary disease, but it was less sensitive (50%) than SAP (80%).[4]

When serum GGT and ALP were used in series, their specificity for the detection of hepatobiliary disease increased to 94%. In a series of 36 dogs with primary or metastatic hepatic neoplasia, 39% had high serum GGT values. Phenobarbital and corticosteroids cause mild (two to threefold) increases in serum GGT in the dog.

In a series of 69 cats with hepatobiliary disease, the largest increases in serum GGT were associated with extrahepatic bile duct obstruction (EHBDO) and cholangiohepatitis. Serum GGT had a higher sensitivity than serum ALP (86% versus 50%, respectively), but lower specificity (67% versus 93%, respectively) for the detection of hepatobiliary disease.[4] In some cats with cirrhosis, EHBDO, or cholangitis, serum GGT may be considerably greater than serum ALP values. In idiopathic hepatic lipidosis, however, serum GGT values may be normal or mildly increased (two-to sixfold), whereas serum ALP values are markedly increased (tenfold).

225.2 PLASMA PROTEINS IN HEPATIC DISEASE

The liver synthesizes many plasma proteins and detoxifies ammonia, the major breakdown product of protein metabolism. The clinical consequences of disruptions in hepatic protein metabolism are decreases in plasma oncotic pressure due to hypoalbuminemia, bleeding tendencies associated with coagulation protein deficiencies, and the development of HE due to ammonia retention.

225.2.1 Albumin

The liver is the exclusive site of albumin synthesis. Because synthesis occurs at 33% of maximum capacity and the serum $t_{1/2}$ of albumin is 8 to 9 days, serum hypoalbuminemia is most often seen in chronic hepatic disorders such as cirrhosis and PSVASs. In cirrhotic dogs, serum hypoalbuminemia, portal hypertension, and avid sodium and water retention lead to the development of ascites. In ascitic animals, serum hypoalbuminemia may reflect both third-party sequestration of albumin in the abdominal fluid and hepatic synthetic failure. Hypoalbuminemia is not specific for hepatic disease and may occur with protein-losing enteropathies, protein-losing nephropathies, exudative cutaneous lesions, vasculitis, or acute blood loss.

Inadequate nutrition can curtail hepatic albumin synthesis. Because albumin is a negative acute phase reactant, systemic inflammatory disease may shut down hepatic albumin synthesis.

225.2.2 Globulins

The serum globulin fraction is composed of immunoglobulins and nonimmunoglobulins. Because the liver synthesizes many of the nonimmunoglobulins including α-globulins and β-globulins, hepatic synthetic failure can be accompanied by serum hypoglobulinemia. However, because many nonimmunogloblins are acute-phase reactants whose production that is increased in response to systemic inflammatory disease, early chronic inflammatory liver disease may be accompanied by hyperglobulinemia.[4,13,14]

Immunoglobulins are not synthesized in the liver but may be increased in chronic inflammatory hepatic disease. A polyclonal increase in γ-globulins has been documented in chronic canine hepatic disease and is seen in 50% of feline cases of chronic cholangiohepatitis. Hypergammaglobulinemia in chronic liver disease may be associated with enhanced systemic immunoreactivity due to abnormal Kupffer cell processing of portal antigens or secondary to autoantibody production. Low titers of antinuclear antibodies have been detected in 50% of dogs with chronic inflammatory hepatic disease.[15] In a series of dogs with chronic inflammatory hepatic disease, 48% had antibodies that reacted with canine liver membrane preparations.[16] Although dogs with positive titers tended to have higher serum ALT and bilirubin values and more severe histopathologic lesions than dogs without antibody responses, it remains to be determined whether these autoantibodies have any role in disease progression.

225.2.3 Coagulation Proteins

The liver plays an important role in hemostasis. Hepatocytes synthesize all of the coagulation factors, except factor VIII, as well as critical inhibitors of coagulation and fibrinolysis (antithrombin III, antiplasmin) and fibrinolytic proteins (plasminogen). In addition, the liver is responsible for clearance and catabolism of activated coagulation factors, plasminogen activators, and breakdown products of fibrinolysis such as fibrin degradation products (FDP). The liver is also the site of vitamin K–dependent activation of factors II, VII, IX, and X and protein C.

Assessment of coagulation status is important in animals with liver disease because altered hemostasis can contribute to clinical manifestations of hepatic disease and complicate invasive diagnostic procedures. The complexity and overlap of the liver's synthetic and clearance functions, however, makes the interpretation of hemostatic testing difficult. The commonly used tests to assess coagulation include determination of prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen, and FDPs. Abnormalities in these coagulation tests in hepatobiliary disease may be indicative of hepatic synthetic failure, vitamin K deficiency, or the presence of a consumption coagulopathy such as disseminated intravascular coagulation (DIC).

Coagulation abnormalities are quite common in dogs and cats with hepatobiliary disease.[4] In dogs with naturally occurring hepatic disease, 50% and 75% had an abnormal PT and APTT, respectively. Specific factor analysis revealed that greater than 90% of the dogs had at least one abnormality. Because factor depletion must be greater than 70% to show prolongation of coagulation times, it is not surprising that many more dogs had abnormalities in the concentration of coagulation factors than had prolongation of PT or APTT. In cats with naturally occurring hepatobiliary disease, 82% had at least one coagulation abnormality.[17] The most common abnormalities were an increase in PT (16 of 22) and low factor VII activity (15 of 22).

Despite the presence of abnormalities in coagulation tests, spontaneous hemorrhage in animals with hepatic disease is rare. Hemorrhage is more likely to occur after a challenge to hemostasis such as venipuncture, hepatic biopsy, or gastric ulceration. Because coagulation tests are relatively poor predictors of an individual's tendency to bleed, one should assume that animals with hepatobiliary disease have a higher than normal risk of bleeding after provocative procedures regardless of the results of coagulation testing.

Assessment of coagulation has prognostic significance in hepatic disease. In dogs with chronic inflammatory liver disease, prolongation of PT and PTT to 1.3 to 1.4 times normal was associated with survival less than 1 week.[18] Although prognostic and useful in managing and predicting the complications of hepatic disease, PT and APPT are not sensitive or specific indicators of hepatic disease and should not be used as screening or diagnostic tests.

Vitamin K deficiency may develop during hepatobiliary disease for several reasons. Prolonged bile duct obstruction interrupts the enterohepatic circulation of bile acids resulting in intestinal bile acid deficiency and resultant fat-soluble vitamin K malabsorption. Oral antibiotics may alter the normal intestinal bacterial flora, resulting in the destruction of vitamin K–generating bacteria. Inadequate dietary consumption of vitamin K, although rarely a primary cause of vitamin K deficiency, may be contributory. This is especially true in disorders such as feline idiopathic hepatic lipidosis, which is marked by prolonged anorexia. Vitamin K is a cofactor in the carboxylation and resultant activation of factor II, VII, XI, and X and protein C. Prolongation of PT is the first coagulation abnormality seen with vitamin K deficiency, because factor VII has the shortest plasma $t_{1/2}$. In vitamin K deficiency, vitamin K–dependent factors circulate in an inactive form. The concentration of these inactive factors can be measured and is referred to as *proteins induced by vitamin K absence or antagonists* (PIVKAs). The presence of increased PIVKAs is more sensitive than changes in PT to detect vitamin K deficiency.[19] When either PIVKAs or prolongation of PT were used to detect vitamin K deficiency, 50% to 75% of cats with naturally occurring hepatobiliary disease had vitamin K deficiency.[19,17] Failure to activate vitamin K–dependent factors also may occur as the result of hepatic synthetic failure. Parenteral administration of vitamin K readily (within 24 to 48 hours) corrects coagulation abnormalities due to vitamin K deficiency, but has little to no effect on coagulation abnormalities due to hepatic synthetic failure.

Due to the liver's central role in coagulation and fibrinolysis, it can be quite challenging to differentiate whether coagulation abnormalities are associated with DIC or are due to severe liver disease. Typically DIC is recognized by prolongation of PT, APTT, decreased fibrinogen, thrombocytopenia, and increased FDPs, all of which may accompany hepatic failure. Increases in PT and APTT may accompany hepatic synthetic failure or vitamin K deficiency. In early liver disease, fibrinogen concentrations may be normal to increased (fibrinogen is an acute-phase reactant), but as hepatic function deteriorates, fibrinogen concentrations typically decrease due to reduced hepatic synthesis. Increases in FDPs have been detected in 14% of dogs with chronic hepatic disease and in 30% of cats with idiopathic hepatic lipidosis.[4,11] These increases may represent impaired hepatic clearance of FDPs.

1426

1427

Both quantitative and qualitative platelet defects accompany hepatobiliary disease. Although quantitative platelet abnormalities have been poorly documented in small animals with hepatic disease, many dogs with chronic hepatic disease have mild thrombocytopenia (120,000 to 180,000). The reason for this thrombocytopenia is unknown. Thrombocytopenia is rare in cats with hepatobiliary disease unless DIC is present. Studies in dogs with hepatobiliary disease have demonstrated the presence of qualitative defects in platelet aggregation.

225.3 BLOOD AMMONIA

The liver is responsible for the majority of ammonia detoxification. Ammonia is generated primarily in the GI tract by bacterial degradation of amines, amino acids, and purines; by the action of bacterial urease on urea; and by intestinal catabolism of glutamine. Ammonia readily diffuses through the intestinal mucosa and into the portal circulation where it travels to the liver. After uptake by hepatocytes, ammonia is detoxified either by enzymatic conversion to urea in the mitochondrial urea cycle or by consumption in the synthesis of glutamine. Urea then undergoes renal excretion. Ammonia, which escapes hepatic metabolism, enters the systemic circulation where other tissues, including the kidney, muscle, brain, and intestines, detoxify it by the formation of glutamine.

Failure of the liver to detoxify ammonia or shunting of portal blood away from the liver results in hyperammonemia. Because the urea cycle operates at only 60% capacity, hepatic failure must be fairly advanced for blood ammonia concentrations to rise. Because intrahepatic or extrahepatic shunting of portal blood directly deposits ammonia in the systemic circulation, blood ammonia concentrations are more sensitive in the detection of hepatobiliary disorders associated with shunting.[4,20] Hyperammonemia also occurs in animals with urea cycle enzyme deficiencies and with pathologic conditions that result in decreased availability of urea cycle substrates. Hyperammonemia has been described in dogs with a deficiency of the urea cycle enzyme, argininosuccinate synthetase, and in cats fed a diet deficient in arginine, an essential substrate in the urea cycle.[21,22]

The biggest obstacle in the clinical use of blood ammonia determinations is the difficulty in sample handling. Samples must be drawn directly into cold heparinized tubes, immediately transferred to the laboratory on ice for refrigerated centrifugation, and preferably assayed within 1 hour. Feline, but not canine, plasma samples may be frozen at −20°C for 48 hours without sacrificing accuracy. Because erythrocytes contain two to three times the amount of ammonia as does plasma, if they are not separated from the plasma immediately or if hemolysis is found in the sample, spurious increases in blood ammonia will result.

Technical limitations aside, blood ammonia determination is important for evaluating dogs and cats suspected of having hepatobiliary disease. Hyperammonemia is an important, although not exclusive, cause of HE and is the only toxin implicated in this condition that can be measured clinically. The presence of hyperammonemia can therefore be used to verify the presence of HE. Not all animals with HE, however, will have abnormal blood ammonia levels. Hyperammonemia also reliably occurs in pathologic conditions associated with significant shunting of portal blood away from the liver. Thus 80% of dogs and 90% of cats with PSVASs demonstrate fasting hyperammonemia. Fasting hyperammonemia occurs less often with chronic parenchymal disease, being abnormal in approximately 50% of dogs with chronic hepatitis.[13] Elevations in blood ammonia are unusual with acute hepatic disease, unless it is fulminant.

The diagnostic value of blood ammonia can be improved by performing an ammonia tolerance test (ATT).[4] In an ATT, a baseline blood ammonia value is determined after a 12-hour fast. The animal is then given an exogenous load of ammonium orally or per rectum and blood ammonia determined postchallenge. In the classic oral ATT, NH_4Cl_2 is given at a dose of 100 mg/kg in a dilute solution (not to exceed a concentration of 20 mg/mL and a total dose of 3 g) and blood ammonia determined 30 minutes later. In the rectal ATT, a warm-water enema is given 12 hours prior to the administration of 2 mL/kg of 5% NH_4Cl_2 via a catheter inserted into the rectum. Samples for blood ammonia are taken at 20 and 40 minutes postchallenge. In normal animals after oral or rectal challenge, blood ammonia should not increase any more than twofold. In animals with hepatic insufficiency or PSVASs, ammonia values generally increase three to tenfold. Virtually all dogs and cats with PSVASs and 90% of dogs with chronic hepatitis have abnormal ATT.[9,11] Rarely an ATT will precipitate HE.

A recent study evaluated a modified oral ATT in which dogs were fed a small test meal supplying 33 kcal/kg (25% of daily metabolizable energy requirement) with a protein concentration of 30.3% dry matter.[20] When blood ammonia concentrations were determined at zero time and 6 hours later, a sensitivity of 81% and 91% was found for the detection of PSVASs. The test had poor sensitivity in detecting dogs with parenchymal hepatocellular disease. Unlike classic ammonia tolerance tests, this provocative test was not associated with adverse side effects such as the induction of vomiting or HE.

225.4 SERUM UREA NITROGEN

Approximately 65% of dogs and cats with PSVASs have a decreased serum urea nitrogen (SUN).[3] Decreases in SUN are thought to arise secondary to decreased urea production in the atrophied liver. Decreased SUN is not specific for liver disease because it can be influenced by hydration status and dietary protein content, GI hemorrhage, glomerular filtration rate, and fluid or solute diuresis.

225.5 BILIRUBIN

Bilirubin is a yellow pigment formed in the reticuloendothelial cell system (RES) by the enzymatic processing of heme. Bilirubin released from RES cells is not water soluble and is transported in plasma reversibly bound to albumin. This unconjugated bilirubin is extracted by the liver and conjugated by esterification with glucuronic acid. Water-soluble conjugated bilirubin is actively secreted against a concentration gradient into the bile. The bilirubin in bile enters the intestinal tract via the bile duct, where it is either excreted unchanged in the feces or is converted to urobilinogen by the action of enteric bacteria. Most of the urobilinogen is further degraded into the brown-pigmented stercobilins. The absence of stercobilins in the feces results in pale-colored acholic stools. Small amounts of urobilinogen enter the portal venous system and undergo enterohepatic circulation. The majority is re-excreted into the bile, but a small amount undergoes urinary excretion.

Icterus is the clinical manifestation of bilirubin retention within tissues (see Figure 225-1). Although less sensitive than serum liver enzymes for the detection of hepatobiliary disease, serum hyperbilirubinemia is more specific. Hyperbilirubinemia occurs when an abnormality in the processing of bilirubin exists and can be divided into three categories: (1) prehepatic, (2) hepatic, and (3) posthepatic. Prehepatic hyperbilirubinemia is associated with increased production of bilirubin due to the need to process large amounts of heme such as occurs during severe hemolytic anemia. It is readily differentiated from hepatic and posthepatic causes by determining hematocrit. Hepatic hyperbilirubinemia is associated with impaired hepatic uptake, conjugation, or excretion of bilirubin. It is seen in hepatic disorders in which severe intrahepatic cholestasis develops. Hepatic hyperbilirubinemia may also accompany severe extrahepatic infections.[23,24] In this condition, referred to as the *cholestasis of sepsis*, circulating cytokines directly inhibit hepatocyte bilirubin transport. In a series of 29 septic cats, 63% had hyperbilirubinemia.[23] Posthepatic hyperbilirubinemia is associated with interruption of flow within the extrahepatic bile ducts.

The differentiation of hepatic and posthepatic icterus can be quite challenging clinically and yet is extremely important because these conditions demand different interventional strategies. Posthepatic hyperbilirubinemia usually requires surgical decompression of the biliary tract, whereas hepatic hyperbilirubinemia is typically treated medically. The clinical differentiation between hepatic and posthepatic hyperbilirubinemia is best made by ultrasound evaluation of the biliary system combined with careful consideration of clinical history, physical examination, and ancillary laboratory testing.

During prolonged cholestasis, excess conjugated bilirubin may become irreversibly bound to albumin. These so-called biliproteins are clinically significant in that they are measured as direct reacting bilirubin, but their $t^1/_2$ approximates that of albumin.[4] Their presence can result in persistently elevated serum bilirubin weeks after the resolution of the underlying cholestatic liver disorder.

225.6 BILE ACIDS

Bile acids are synthesized exclusively in the liver from cholesterol. After conjugation to either taurine or glycine, bile acids are excreted into bile and collected, stored, and concentrated in the gallbladder. After ingestion of a meal, cholecystokinin release stimulates gallbladder contraction and the transport of bile acids into the intestine. In the intestinal lumen, bile acids aid in the solubilization and absorption of fats. When the bile acids reach the ileum, they are efficiently transported back into the portal circulation from which they are re-extracted by the hepatocyte sinusoidal bile acid transporter. This enterohepatic circulation of bile acids operates at 98% efficacy.

Disruption of the enterohepatic circulation of bile acids results in increases in the concentration of total serum bile acids (TSBAs). In normal animals, TSBA concentrations are determined by the spillover of bile acids that escape from the enterohepatic circulation. During fasting, when the enterohepatic circulation of bile acids is low, TSBAs are low. After a meal, bile acids are released into the intestines and subsequently absorbed into the portal circulation. Increased portal vein bile acid concentrations are reflected in a transient elevation in TSBAs. This endogenous challenge to the enterohepatic circulation of bile acids is used clinically. In a typical bile acid test, TSBAs are determined after a 12-hour fast, a test meal is fed and then postprandial TSBAs determined 2 hours later.

The most commonly used method for the determination of TSBAs is an enzymatic method that relies on the reaction of 3-α-hydroxy bile acids with bacterial 3-α-hydroxysteroid dehydrogenase. Normal values for fasting TSBA concentrations using this method are 1.7 ± 0.3 μM and 2.3 ± 0.4 μM in cats and dogs, respectively. Two-hour postprandial values are 8.3 ± 2.2 μM in the dog and 8.3 ± 0.3 μM in the cat.[4] Sample collection for this assay is easy because serum bile acids are stable even at room temperature. Hemolysis and lipemia should be avoided because they interfere with the assays spectrophotometric endpoint.

Numerous studies have demonstrated the efficacy of fasting and postprandial TSBAs in the diagnosis of feline and canine hepatobiliary disease and PSVASs.[3,4] In a series of 108 cats with hepatobiliary disease, when cutoff values of greater than 15 μM were used as abnormal, fasting TSBAs were more specific (96%) than increases in serum ALP, ALT or GGT in predicting the presence of hepatobiliary disease. The sensitivity at this cutoff value (54%) was about the same as for serum enzyme determination. The determination of postprandial TSBAs using a cutoff of greater than 20 μM as abnormal improved both the sensitivity (100%) and the specificity (80%) of bile acid testing in the detection of feline hepatobiliary disease. Postprandial TSBAs had a greater sensitivity than fasting TSBAs for the detection of all categories of feline hepatobiliary disease except hepatic necrosis.

In a series of 107 dogs with histologically confirmed hepatic disease, the specificity of fasting TSBAs using a cutoff of greater than 5 μM as abnormal was 83%.[4] Using a cutoff of greater than 15 μM as abnormal, postprandial TSBAs had a specificity of 89% and a sensitivity of 82%. When cutoff values for abnormal fasting and postprandial TSBAs were increased to greater than 20 μM and greater than 25 μM respectively, the specificity of both tests was 100%. Sensitivity at these cutoff values was 59% and 74% for fasting and postprandial samples, respectively. At the higher cutoff values, neither fasting nor postprandial TSBAs

outperformed the other. A notable exception was improved performance of postprandial TSBAs in the detection of inactive cirrhosis or PSVASs.

Maltese dogs may have increased postprandial TSBAs in the absence of hepatobiliary disease.[25] In a screening of 200 Maltese dogs, 79% had postprandial TSBAs above the reference range using the enzymatic method. Nine dogs with abnormal postprandial TSBAs had normal rectal ATT and no evidence of hepatobiliary disease on hepatic biopsy. Two dogs with abnormal postprandial TSBAs had abnormal ATT and PSVASs. The cause of increased postprandial TSBA values in Maltese dogs with normal liver biopsies remains undetermined.

A number of factors that influence the enterohepatic circulation of bile acids in normal animals can affect TSBA values.[4] These include the completeness of gallbladder emptying, the rate of gastric emptying, intestinal transit rate, the efficiency of ileal bile acid reabsorption, and the frequency of enterohepatic cycling. Inadequate fat or amino acid content in the test meal or consumption of an insufficient amount of food can result in failure of cholecystokinin release and gallbladder contraction. In general it is recommended that the animal eat a meal of regular dog or cat food, although 2 teaspoons of food for pets less than 10 lbs and 2 tablespoons for larger animals has been reported to be adequate. Visual confirmation of meal consumption is mandatory. The presence of concurrent disease that delays gastric emptying may result in failure to stimulate gallbladder contraction. Alterations in intestinal transit time so that the movement of conjugated bile acids to the ileum is delayed can result in less than optimum timing for determination of the postprandial values. Severe ileal disease can result in decreased bile acid reabsorption and inadequate challenge to the enterohepatic circulation. The presence of small bowel overgrowth leads to bacterial deconjugation of bile acids and decreased ileal absorption of bile acids.

Occasionally, fasting TSBA concentrations are higher than postprandial values. This happens when interdigestive gallbladder contraction occurs during the course of the fast preceding the test. It may also be associated with individual variations in gastric emptying, response to cholecystokinin release, and intestinal transit time.

The interpretation of abnormal TSBA is subject to a number of limitations. First, TSBAs are not capable of discriminating one hepatobiliary disease from another. A second limitation of TSBA determination is that little, if any, correlation exists between the severity of histologic changes or the degree of portosystemic shunting and the extent of TSBA elevation. A TSBA value is either normal or abnormal. When evaluating serial determinations of TSBAs to monitor disease progression or response to therapy, only a return to normal can be used as a reliable indicator of clinical remission.

225.7 CARBOHYDRATE METABOLISM

The major function of the liver in carbohydrate metabolism is to maintain normoglycemia during the fasting state. The liver has a large reserve for maintaining glucose homeostasis so that greater than 70% of hepatic function must be lost before hypoglycemia occurs. Hypoglycemia occurs most often in acute fulminant hepatic failure and in small breed dogs with PSVAs.[3] In acute hepatocellular injury, hypoglycemia may be a relatively early indicator of severe hepatic failure. Up to 35% of dogs with congenital PSVAs are periodically hypoglycemic. In these dogs, hypoglycemia may be due to impaired hepatic glucose production, decreased hepatic glycogen stores, reduced responsiveness to glucagons, or a combination of these factors. Inadequate glycogen stores may reflect immaturity of the carbohydrate metabolizing enzyme systems or be a consequence of chronic stimulation of glycogenolysis. Hypoglycemia is a rare complication of end-stage chronic inflammatory liver disease and is a negative predictor of survival.[18]

Hypoglycemia may occur as a paraneoplastic syndrome in dogs with hepatic neoplasia.[8] Proposed mechanisms for the hypoglycemia include increased glucose use by the tumor or secretion of an insulin-like substance that inhibits gluconeogenesis and promotes glycogenolysis. Insulin levels, when measured, have been normal.

Glycogen storage diseases may cause hypoglycemia.[11] In dogs, a congenital deficiency in amylo-1,6-glucosidase has been associated with fasting hypoglycemia and the development of hepatomegaly due to glycogen accumulation.

225.8 CHOLESTEROL AND LIPID METABOLISM

The liver has several functions in lipid metabolism. Plasma fatty acids released from adipose tissue are extracted by the hepatocytes, after which they are either converted to triglycerides or undergo mitochondrial β-oxidation. Triglycerides are either stored or packaged as very low–density lipoproteins and released into the vasculature. The liver also extracts chylomicron remnants and low-density lipoproteins from plasma. This is the major route by which cholesterol enters into the liver, although the liver is also capable of cholesterol synthesis. Hepatic cholesterol can be esterified and then packaged and secreted in lipoproteins or stored in the liver. The majority of unesterified (free) cholesterol in the liver undergoes biliary excretion.

Hypercholesterolemia is associated with increased hepatic synthesis, decreased biliary excretion of cholesterol, or both. In the dog and cat, EHBDO is accompanied by increases in serum cholesterol. Hypocholesterolemia occurs in approximately 62% of dogs and 67% of cats with PSVAs and may be due to decreased cholesterol synthesis or increased incorporation of cholesterol into bile acids.[3] Hypocholesterolemia also occurs with late-stage chronic liver disease in dogs.[13]

225.9 URINALYSIS

Between 40% to 74% of dogs and 15% of cats with PSVAs have ammonia biurate crystalluria.[3] Repeated examination of fresh urine specimens may be necessary to document the presence of these crystals. Uric acid, a by-product of purine nucleotide catabolism, is normally converted to allantoin by hepatic urate oxidase. In hepatic disease, a deficiency of this enzyme may lead to hyperuricemia. In the presence of concurrent hyperammonemia, increased concentrations of both ions appear in the urine, resulting in the precipitation of ammonia biurate crystals.

Bilirubinuria is the presence of conjugated bilirubin in the urine. Bilirubinuria in the dog is not abnormal, because dogs have a low renal threshold for bilirubin and their renal tubular epithelium is capable of bilirubin production. Because cats have a high renal threshold for bilirubin and feline kidneys do not make bilirubin, feline bilirubinuria is always abnormal and suggests the presence of a hepatobiliary or hemolytic disorder.

225.10 HEMATOLOGIC ABNORMALITIES

Anemia may be present in dogs or cats with hepatobiliary disease. Regenerative anemia is most often associated with blood loss. Although spontaneous bleeding associated with coagulopathies is rare in animals with hepatic disease, blood loss may occur after provocative procedures or secondary to GI ulceration. Nonregenerative anemia, a more common finding in hepatic disease, is usually normocytic and normochromic and often associated with inefficient use of systemic iron stores (anemia of chronic disease). A microcytic, hypochromic, nonregenerative anemia should prompt consideration of chronic GI blood loss. Erythrocyte microcytosis occurs

in dogs and cats with congenital PSVAs,[3] in dogs with acquired shunting secondary to cirrhosis and in some cats with idiopathic hepatic lipidosis. Studies investigating the cause of this microcytosis in dogs with PSVAs have documented a relative iron deficiency that may be associated with impaired iron transport.[26] Target cells and poikilocytes may be seen in dogs and cats with hepatic disease. These morphologic changes may be associated with alterations in the erythrocyte plasma membrane lipoprotein content resulting in altered cell deformability.

225.11 HEPATIC BIOPSY ACQUISITION AND INTERPRETATION

Because patterns of clinicopathologic abnormalities do not reliably differentiate one form of hepatic disease from another, it is often necessary to obtain hepatic tissue for histopathologic or cytologic evaluation. The indications for examination of hepatic tissue include persistent increases in serum liver enzymes, increased serum bile acids or bilirubin, unexplained abdominal effusion or ascites, unexplained hepatomegaly, to assess response to therapy or disease progression, and to evaluate for breed-specific hepatopathies. Because the most common complication encountered in the procurement of hepatic tissue is hemorrhage, before undergoing hepatic tissue acquisition, all dogs and cats should have a PT, APTT, and platelet count assessed. Determination of PIVKAs and buccal mucosal bleeding time may improve the sensitivity of detecting bleeding tendencies. Due to the high frequency of vitamin K deficiency in hepatic disease and the ease with which it is treated, many clinicians routinely pretreat all patients with parenteral vitamin K_1 24 hours prior to hepatic biopsy. Acquisition of hepatic tissue is contraindicated in the presence of a severe coagulopathy, although some animals may be biopsied safely after the administration of fresh frozen plasma to supply deficient coagulation factors.

In general, hepatic biopsy is preferred over fine needle aspirate (FNA) to characterize liver disorders. However, in animals with bleeding disorders or those with large cavitary lesions or suspected abscesses, ultrasound guided fine needle aspiration (22 gauge needle) can safely be performed with minimal danger of hemorrhage or spread of infection. In studies done comparing FNA to hepatic biopsy, complete agreement is typically seen in around 30% of cases. While FNAs may be helpful in identifying vacuolar or neoplastic disease such as lymphoma, they frequently miss the presence of necroinflammatory or vascular disease.

1429
1430

Hepatic biopsy can be obtained by ultrasound-guided needle biopsy, laparoscopic biopsy, or wedge biopsy by laparotomy. The advantages of the latter two methods are the ability to grossly evaluate the liver at the time of biopsy, the acquisition of relatively large tissue samples, and the identification and control of postbiopsy hemorrhage. An obvious disadvantage of these techniques is their invasive nature and, in the case of laparoscopy, the need for special equipment and technical expertise. Ultrasound-guided needle biopsy using automated spring-triggered biopsy needles has proven to be a safe, effective, minimally invasive means of obtaining biopsy material in most animals. Ultrasound guidance allows accurate sampling of focal lesions and permits visualization of the needle tract to minimize complications. When obtaining ultrasound-guided needle biopsy, particular care should be taken to obtain adequate samples (two to three specimens that fill at least three fourths of the 18-(in cats) or 16-(in dogs) gauge biopsy needle chamber should be obtained). Complications of ultrasound-guided needle biopsy (other than hemorrhage) are rare but include perforation of biliary structures, pneumothorax, and bacterial peritonitis. When an intrahepatic abscess is suspected or a highly vascular lesion is present, hepatic needle biopsy is contraindicated due to the high probability of infection and bleeding, respectively. Postbiopsy, animals should be monitored with ultrasound for the presence of postbiopsy bleeding and have PCV checks for up to 6 hours after the procedure.

Because the tissue obtained by wedge or needle biopsy represents only a tiny fraction (maybe 1/10,000) of the entire liver, one of the major limitations of hepatic biopsy is sampling error. Sampling error arises due to uneven distribution of lesions in what appears by diagnostic imaging to be diffuse disease. A recent study demonstrated significant discordant between the morphologic diagnoses obtained when needle and wedge biopsies from the

same animal were evaluated by the same pathologist.[28] This discordance most likely reflects sampling error. This same study also demonstrated that individual pathologists disagree on the morphologic diagnosis 44% and 65% of the time when the same wedge or needle biopsies, respectively, were evaluated. This emphasizes the need for a constant stream of communication between clinician and hepatic histopathologists. Clinicians should always be the final judges as to whether the histopathologic morphologic diagnosis fits with the clinical picture. Opinions from more than one pathologist on hepatic biopsy material may be necessary to arrive at an accurate morphologic diagnosis. In addition, internist and pathologist should both be willing to accept the limitations of hepatic biopsy and be prepared to rebiopsy, if warranted.

To fully appreciate the value of histopathologic evaluation of the liver, one must understand what information to reasonably expect from tissue samples.[29] One should expect the sample to determine the category of disease (necroinflammatory, neoplastic, vacuolar, or vascular), to define the extent of disease (mild, moderate, or severe) and to access the chronicity of the lesion (presence of fibrosis, type of cellular infiltrate). One should not expect every hepatic biopsy to provide a etiologic diagnosis. The biopsy, however, may provide clues as to cause. Special stains can help to identify infectious agents or determine if copper overload exists. Samples for anaerobic and aerobic culture may confirm suspicion of primary or secondary bacterial infection. Certain infectious diseases or toxins may cause lesions with characteristic anatomic distributions (e.g., passive congestion and acetaminophen toxicity cause centrilobular lesions), whereas infections such as salmonellosis or toxoplasmosis cause focal or multifocal lesions. Vacuolar change indicates cytoplasmic accumulation of lipid, water (hydropic degeneration), or glycogen (steroid hepatopathy). The liver can have a similar histologic reaction pattern to different insults. Macroscopic or microscopic PSVAs, primary hypophasia of the portal vein and arteriovenous fistula cause a characteristic histologic pattern (hepatic cord atrophy, portal vein attenuation, and portal arteriolar proliferation). Chronic inflammatory lesions provide the biggest challenge in interpretation, because the liver responds to many chronic insults (whether caused by toxins, infection, or immune stimulation) with the same reaction pattern. The important points to remember in evaluating inflammatory biopsies is to pay attention to the type of inflammatory cell present (neutrophilic: acute, active, or both; eosinophilic: allergic or parasitic; lymphoplasmacytic: subacute to chronic), whether inflammation breaks through the limiting plate (the disease is more severe if it does), and to note the extent of fibrosis (confined to portal regions, bridging portal tracts). Bridging fibrosis is consistent with severe disease and is a negative prognostic factor.[18]

225.12 DIAGNOSTIC IMAGING

225.12.1 Radiography

Radiography can be used to assess changes in the size and opacity of the liver.[30] Diffuse hepatomegaly is indicated by rounding of the liver edges, extension of the hepatic shadow beyond the costal arch, and caudal displacement of the stomach axis. Hepatomegaly may occur due to congestion, infiltrative disease (neoplasia, lipidosis, glycogen accumulation, amyloidosis), inflammatory disease, RES cell hyperplasia, or extramedullary hematopoiesis. Focal hepatomegaly can be discerned by observing displacement of the structures bordering the liver, and it may occur with cysts, granulomas, neoplasia, regenerative nodules, hematomas, or abscesses. Microhepatica is visualized radiographically by a decreased size of the hepatic shadow and a shift of the gastric axis to a more upright orientation with cranial displacement. Microhepatica is observed with hepatic atrophy and fibrosis.

Normally the liver is visualized as a homogenous soft tissue opacity. Cholelithiasis or choledocholithiasis may be visualized as mineralization in the liver. The former is recognized as a discrete round opacity in the cranial right ventral liver shadow, and the latter is seen as diffuse mineralization. Focal mineralization may also be

seen with chronic gallbladder infection or neoplasia, granulomatous lesions, abscesses, resolving hematomas, and within regenerative nodules.

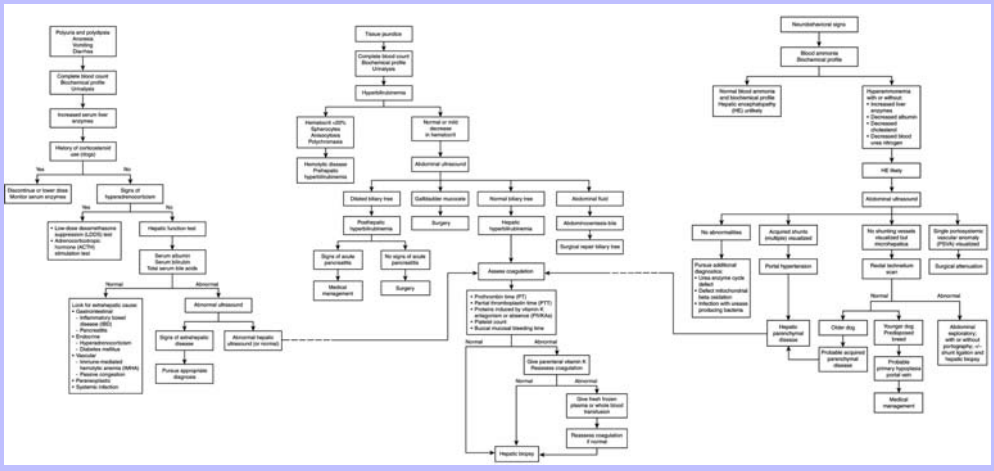
Gas opacities in the liver may be associated with hepatic abscesses, emphysematous cholecystitis, or after long-term bile duct obstruction. The finding of gas within the portal vessel indicates the entry of GI gas or infection with gas-producing organisms and is a grave sign seen with gastric torsions and severe necrotizing gastroenteritis.

Radiographic contrast imaging of the portal venous system is used to localize PSVAs. It can be accomplished via three methods. The first, cranial mesenteric arteriography, involves cannulation of the cranial mesenteric artery via the femoral artery and injection of iodinated contrast followed by rapid fluoroscopic imaging. These studies are fraught with technical difficulties and are seldom performed. The second method, splenoportography, involves injection of contrast agent directly into the spleen, either percutaneously or at the time of laparotomy. Complications include splenic infarction and hemorrhage. The best method to demonstrate PSVAs is operative mesenteric portography. This involves intraoperative jejunal vein catherization and injection of iodinated contrast.

1430

1431

Figure 225-1 Laboratory diagnosis of hepatobiliary disease.



1431

1434

Colorectal scintigraphy is used in small animals for the detection of PSVAs.[31] In these studies, a small amount of ^{99m}technetium pertechnetate is administered rectally and absorbed across the colon into the portal venous system. In the normal dog, radioactivity is visualized in the liver within 10 to 22 seconds and subsequently moves to the heart and lungs. In animals with PSVAs, radioactivity reaches the heart and lungs first or at the same time as the liver. Rectal technetium scans are abnormal in dogs with macroscopic PSVAs or acquired shunts from chronic parenchymal disease and normal in dogs with microvascular dysplasia or parenchymal disease without acquired shunts.

225.12.2 Ultrasonography

Ultrasonography enables differentiation between focal and diffuse disease, evaluation of alterations in hepatic parenchyma in diffuse disease, evaluation of the biliary system and portal vasculature, and procurement of tissue for hepatic histopathology.[32,30]

The normal liver has a homogenous echogenicity that is isoechoic to slightly hyperechoic to the renal cortex. It has sharp, smooth edges and contains numerous variably sized circular and tubular anechoic structures that represent hepatic and portal veins. Hepatic arteries and intrahepatic bile ducts are not routinely visualized. The gallbladder is seen as an anechoic structure with thin walls varying from oval to pear shaped. It may be bilobed in the cat. The common bile duct can be visualized as a tubular anechoic structure just ventral to the portal vein. During hepatobiliary disease, changes in hepatic size, vascularity, and echogenicity may occur. It must be emphasized that few hepatic lesions have diagnostic sonographic features and that a normal hepatic ultrasound does not rule out the possibility of diffuse hepatic disease.

The determination of liver size by sonography is, at best, subjective. A large liver may be easily imaged and has rounded edges. There will be a relatively large distance between the diaphragm and stomach. A small liver may be difficult to image, with a narrow distance identified between the diaphragm and stomach.

In diffuse hepatic disease the liver may appear hyperechoic or hypoechoic. The hyperechoic liver is brighter than the renal cortices. Portal vein margins become indistinct in the hyperechoic liver. Increased echogenicity may accompany fibrotic liver disease, lipidosis, corticosteroid hepatopathy, or hepatic neoplasia (lymphoma, bile duct adenocarcinoma). The fibrotic liver can be distinguished from the other causes of increased echogenicity by its small size, the presence of regenerative nodules, and its association with ascites. In a series of cats with various hepatobiliary disorders, the finding of a hyperechoic liver that was isoechoic to falciform fat was highly suggestive of the presence of hepatic lipidosis. A hypoechoic liver is less echogenic than the renal cortices and has enhanced visualization of portal vasculature. It may accompany moderate to severe suppurative hepatic disease, passive congestion, or hepatic lymphoma.

The sonographic appearance of hepatic lymphoma can be quite variable. The liver may be diffusely hyper-or hypoechoic. There may be focal or multifocal poorly circumscribed hypoechoic masses or well-circumscribed hyperechoic nodules surrounded by areas of hypoechogenicity (so called target lesions).

A variety of focal hepatic lesions can be recognized with ultrasonography. Hepatic cysts appear as round, smooth-walled, anechoic structures with acoustic enhancement. Biliary cysts appear as thin-walled, circular, anechoic structures. Hematomas have a variable appearance, depending on their state of resolution. Early hematomas are hyperechoic and progress to hypoechoic; once they mature, they are anechoic. They may have areas of mineralization. Regenerative nodules also have a variable appearance. They may be hypoechoic, isoechoic, hyperechoic, or have mixed echogenicity. Variably sized multiple hypoechoic areas often exist; some areas may appear anechoic if necrosis occurs within them. Abscesses or granulomas have a variable appearance, depending on their cellular composition and duration. Early abscesses are hyperechoic with poorly defined margins. As they mature they become more hypo-to anechoic and may have mixed echogenicity. The presence of gravity-dependent hyperechoic cellular material may be demonstrated. Occasionally they may contain gas or mineralization. Some posterior acoustic enhancement may occur.

Primary hepatic neoplasia may have a variable appearance.[8] It usually is a large, solitary, moderately circumscribed mass that bulges beyond the normal liver margins with an echo texture similar to normal liver.

Metastatic neoplasia appears as one or more spherical lesions that may be hypoechoic, hyperechoic or isoechoic. It may also appear as a target lesion.

Ultrasonography is important in determining the presence of EHBDO.[32] The first indication of EHBDO is distention of the gallbladder with loss of tapering of the neck into the cystic duct. This occurs 24 hours after experimental bile duct ligation in the dog. The common bile duct distends by 48 hours postligation. Extrahepatic bile ducts dilate by 72 hours and are visible as many tortuous anechoic structures at the portal hepatis between the gallbladder and the pancreas. Intrahepatic bile ducts distend by 1 week and are seen as tortuous, irregularly branching anechoic structures with echogenic walls throughout the liver. In cats, distention of the common bile duct to greater than 5 mm is consistent with EHBDO.[33] Ultrasound also enables visualization of the cause of the obstruction that may be associated with intraluminal (neoplasia, strictures, choleliths) or extraluminal (pancreatitis, neoplasia) disorders.

Abdominal ultrasonography has an accuracy rate of about 90% for the diagnosis of PSVAs.[31] Animals with PSVAs have small livers with a decrease in portal vascular structures and may have bilateral renomegaly and uroliths. The abnormal connection between the portal vein and the systemic vasculature may be visualized. In general, intrahepatic shunts are easier to visualize than extrahepatic shunts. Portoazgous shunts are the most difficult extrahepatic shunts to identify. Doppler capabilities can enhance the ability to detect extrahepatic shunts. Dogs with extrahepatic shunts have high-velocity turbulent flow in the portal vein, and preliminary studies show a decreased portal vein size as assessed by comparison of the portal vein with the aorta or caudal vena cava. Acquired portosystemic shunts are more difficult to visualize by ultrasound but can be seen in the retroperitoneum near the kidneys or medial to the spleen. Other signs of portal hypertension such as ascites, decreased or reversed portal blood flow, and microhepatica are seen when acquired shunts are present.

Hepatic arteriovenous fistulas can be seen with as tortuous, tubular, anechoic structures within or adjacent to the liver. Doppler-assisted ultrasonography demonstrates areas of turbulent blood flow. The hepatic artery and portal vein branches may be dilated and tortuous. Celiac arteriography is used to identify arteriovenous fistulas and to define the limits of surgical resection.

226 CHAPTER • 226 General Principles in the Treatment of Liver Disease

Jan Rothuizen

226.1 INTRODUCTION

Many generally accepted and clinically used medications for liver disease lack critical evaluation of their effectiveness. A scientific basis for proof of effect of a medication may be obtained in different ways.

First, there may be a well understood and direct connection with the pathophysiologic basis of the disease. An example is the use of thyroid hormone to treat hypothyroidism caused by decreased production in the thyroid glands. A firm and direct relationship should be present between cause of disease and medication to accept such as a basis. A proven pathophysiology-based therapy in human medicine supports the use for comparable lesions in veterinary medicine. An example is ursodeoxycholic acid (UDCA) therapy in nonobstructive cholestatic diseases. Proof in humans, however, is not proof for dogs or cats and does not eliminate the need for veterinary studies.

The second way a therapy can be accepted as scientifically based is when an effect has been proven in clinical trials. The best method is a randomized, double-blind, placebo-controlled study. No reports exist in the literature of any randomized, placebo-controlled, double-blind studies on the effect of a treatment of liver disease of dogs or cats. Because few, if any, clinics have a sufficient case load to perform a number of such studies within a reasonable time, the only way to test therapies for liver diseases is to perform multicenter studies. Bearing in mind that sound studies on the effectiveness of a drug can only be performed by evaluating one (additional) drug per trial, it is clear that a lot of work must be done. Accepting the need for multicenter studies identifies the need for standardization of the nomenclature and diagnostic criteria for diseases. The diagnosis of the majority of canine and feline liver diseases depends largely on the histologic evaluation of liver tissue, obtained by one of several possible biopsy techniques. It is well known that evaluation of one liver specimen by different histopathologic produces different interpretations, often even a range of different diagnoses. Moreover, in different countries or continents, the same disease may be known under different names without clinicians realizing that it is one disease. The need for standardization of diagnostic criteria of diseases and stages of disease, as well as the unification of nomenclature, has recently been recognized by the World Small Animal Veterinary Association (WSAVA), in cooperation with the American and European Colleges of Veterinary Internal Medicine, ACVIM and ECVIM. This group has agreed on the standardization of nomenclature and histopathologic interpretation of liver tissues of known liver diseases of dogs and cats. The results are being published in a book (see www.wsava.org), providing descriptions and color slides of histologic features. These standards will be updated every 3 years. The availability of standardized criteria and nomenclature will aid multicenter studies on liver diseases.

226.2 DRUGS USED FOR TREATMENT OF LIVER DISEASES

226.2.1 Glucocorticoids (Prednisone and Prednisolone)

The use of corticosteroids has been common practice in human medicine for 30 to 40 years. Mononuclear inflammatory cells, lymphocytes, and plasma cells in chronic hepatitis leads to the assumption that (auto-) immune reactions were the main cause of ongoing, chronic hepatitis leading to the development of cirrhosis. The recognition of hepatitis viruses A and B limited this category to nonA-nonB hepatitis and later

nonA-nonB-nonC hepatitis after discovery of hepatitis C virus. These terms have been abandoned in human medicine. Many different viruses cause many different forms of hepatitis. Only a small and well-defined group remains classified as autoimmune hepatitis that is treated with corticosteroids. The different forms of viral hepatitis require specific antiviral treatment or only supportive treatment. Recognition of new canine viral and metabolic causes may lead to development of specific treatments for different forms of hepatitis that are now taken together as idiopathic hepatitis. Presently, steroid therapy is the best-documented and most generally used therapy for chronic hepatitis. Many anecdotal reports exist. Only one publication[1] reports the evaluation of the effect of glucocorticoids on the survival in a large series of dogs with chronic hepatitis in which there was a highly significant increased survival found in treated compared with untreated dogs. Complete remission was described, and no relapse occurred when recovery from hepatitis was reached. This report was a retrospective, uncontrolled study. The general experience of veterinary hepatologists is that glucocorticoids are often effective in treating chronic hepatitis in dogs. Prednisone needs to be metabolized into prednisolone by the liver. It is logical to use prednisolone in case of liver disease. Prednisolone can be regarded as a treatment of first choice for idiopathic chronic hepatitis. For cases in which a defect in copper metabolism is known, leading to copper storage and oxidative damage of the liver, specific chelating therapy instead of steroids is indicated. Corticosteroids have anti-inflammatory effects but also antifibrotic and choleretic effects. Their principle indication remains immunomodulation. For stimulation of choleresis, UDCA is much more effective, and the weak effect on formation of fibrosis does not justify the use of corticosteroids for treatment of fibrosis without mononuclear inflammation.

Glucocorticoids are contraindicated for infectious diseases of the liver and biliary system. They should be reserved for chronic hepatitis with mononuclear inflammation of which no infectious cause is known. Toxins, viruses, and so on may cause acute hepatitis, but the specific cause remains unknown in most cases. Most acute hepatitis cases recover spontaneously without treatment or with only symptomatic support (antiemetics, fluid therapy). Given the similarities between hepatitis in dogs and other species in which hepatitis is nearly always caused by viral infections, at least some dogs with acute hepatitis may have an active viral infection. This may be overcome by the immune response so that the dog recovers or in some cases develops a chronic inadequate (auto-) immune response. In the chronic stage of disease, immunosuppression may help to reduce the inflammatory effects without treating the underlying cause. In acute cases such medication is contraindicated. The author has seen a number of dogs with acute hepatitis develop a sudden fatal deterioration when corticosteroids were given. Side effects of glucocorticoids are detailed in Chapter 242.

1435
1436

226.2.2 Azathioprine

If immunosuppression is the desired action of therapy and glucocorticoids yield unacceptable adverse effects, azathioprine is an alternative drug. By combining azathioprine and glucocorticoids, the steroid dose can be reduced so that side effects can be avoided or made acceptable. A disadvantage of azathioprine is bone marrow suppression. It is more expensive than glucocorticoids and is also potentially toxic to humans. The owner should use gloves during administration, and tablets should be chosen so that they do not need to be broken, thereby exposing the owner to inhalation of small particles. No studies have reported the effects of azathioprine in liver diseases. Azathioprine is not a preferred drug to treat liver diseases other than in rare cases that do not tolerate glucocorticoids. Azathioprine should be avoided in cats because severe side effects are common.[2]

226.2.3 Ursodeoxycholic Acid

UDCA is one of the natural bile acids in the enterohepatic circulation.[3] It is synthesized and manufactured as tablets or capsules (e.g., Actigall, Ursochol) that are used in both human and veterinary medicine. Bile acids are produced and conjugated in the liver, and they are kept very efficiently in the enterohepatic cycle. The primary bile acids (those primarily formed in the liver) are transformed by intestinal bacteria into secondary and tertiary bile acids so that a mixture of bile acids circulates. Some bile acids are highly toxic, especially in the liver where they are concentrated. The less hydrophilic the more toxic the specific bile acid tends to be[4]; the most toxic bile acid is lithocholic acid. The hydrophilic UDCA is nontoxic in concentrations encountered in normal or diseased liver. Toxic bile acids have a number of negative effects. They induce apoptosis[5] of hepatocytes by activation of the Fas receptor, which activates intracellular signaling of the apoptosis pathway. Liver cell necrosis is also induced by altered permeability of the mitochondrial membrane due to high concentrations of bile acids. Disruption of the mitochondrial electron transport chain leads to formation of free radicals and oxidative damage to the cells.

The proposed positive actions of the nontoxic bile acid UDCA are fourfold. UDCA has been shown to prevent cells from entering the apoptosis pathway and to prevent mitochondrial damage. The exact mode by which these actions occur is not known. One explanation is that toxic bile acids, such as lithocholic acid, circulate in the enterohepatic circulation and accumulate in the liver cholestasis. They are displaced from the bile acid pool by constant enrichment of the pool with UDCA. Another explanation is induction of an increased bile flow by UDCA. Active bile acid excretion into the bile canaliculi by hepatocytes is one of the main mechanisms in which bile is formed because excretion of bile acids against a huge concentration gradient is followed by water, building the flow of bile.[6] Addition of external bile acids to the pool induces the need for hepatocytes to excrete more bile acids, thereby enhancing the bile flow and efflux of toxic bile acids. The enhanced bile flow explains also why UDCA is contraindicated in cases of extrahepatic bile duct obstruction. The third action of UCDA is modulating the immune system, resulting in reduction of the immune response, which may be favorable in cases where autoimmunity is part of the trigger for ongoing disease.

Finally, UDCA has recently been shown to increase the production of glutathione (GSH)[4] and metallothionein in hepatocytes, which could help to prevent oxidative damage.

Both dogs and cats are given 15 mg/kg/day, divided over two doses. UDCA has virtually no side effects in therapeutic doses. It is therefore a safe drug that at least does no harm to the patient. However, no published studies are available on the clinical effect of UDCA in dogs or cats. Although in theory UDCA may be used in a wide spectrum of diseases, it has only been proven effective in human chronic cholestatic disease such as primary biliary cirrhosis.[7–9] At present, the main indication in analogy to use in human medicine seems to be chronic severe cholestatic diseases such as destructive cholangiolitis in dogs and lymphocytic cholangitis in cats.

226.2.4 Antioxidants

Oxidative stress and damage of cells by free oxygen radicals is a mechanism extensively studied in recent years. Factors such as reduced blood perfusion, inflammatory reactions, and accumulation of copper or iron in the liver may be incriminated in the development of hepatocyte necrosis and hepatitis. Copper toxicosis results in chronic hepatitis or hemolysis, specifically by oxidative damage caused by free copper in the cell. Oxidation is also the principle mechanism by which phalloidin,[9–11] produced by the mushroom *Amanita*

phalloides and acetaminophen[12–14] may cause severe, sometimes fulminant liver failure. Oxidative stress is also a key step in the pathogenesis of ethanol-associated liver injury in man. The main sources of free radicals are hepatocyte mitochondria, cytochrome P450 enzymes, and endotoxin-activated macrophages (Kupffer cells).[15] Free radicals take up electrons from neighboring molecules, causing oxidative damage to lipids, proteins, and DNA. The normal cellular defense mechanisms against oxidative stress are superoxide dismutase (SOD), catalase, and GSH peroxidase. Depletion of GSH may cause exhaustion of part of the cellular defense and oxidative damage. Nutritional vitamins C and E act also as free-radical scavengers.

It is logical to separate the liver diseases in which oxidation is the principle event leading to tissue damage and inflammation (such as amanita and acetaminophen intoxication and copper storage diseases) and liver diseases (such as viral or idiopathic hepatitis) where oxidative stress may be one factor in a series of events but not the key factor. The beneficial effect of antioxidant therapies has been well-proven in amanita-and acetaminophen-induced damage, both in experimental animal models[9,11–13] and in human[10] and veterinary medicine.[14] For copper storage diseases in which free intracellular copper is the trigger for free-radical formation, the best therapy remains direct elimination of free copper by copper-chelating drugs such as penicillamine. No reports exist on the effect of antioxidant therapy in copper storage diseases of dogs; therefore clinicians have no reason to consider such therapies in addition to chelating drugs. The only event in copper storage diseases in which use of antioxidants is logical is hemolytic crisis that has at least been described in Bedlington terriers, similar to humans with Wilson's disease. Such an acute and severe oxidative stress requires all possible medications available to save the animal, and chelating therapy together with antioxidants may be life saving. The use of antioxidant therapy in other liver diseases is much more speculative, because oxidative damage is only one factor in a complex pathogenesis. Several antioxidants may be used as therapy; however, no scientific reports exist on efficacy and use is speculative. The main antioxidants are vitamin C, vitamin E, silymarin, and S-adenosyl-L-methionine (SAMe). In addition, zinc and UDCA have antioxidant function.

1436

1437

226.2.5 Vitamins C and E

These vitamins are normally synthesized by dogs and cats, whereas humans cannot make vitamin C (ascorbate). Vitamin C is one of the physiologically soluble intracellular antioxidants. It is not known whether deficiency can occur in disease, and no reports exist regarding the clinical effect of supplementation. In LEG rats with hepatic copper storage due to Wilson's disease, addition of vitamin C to the diet prolonged their lives and retarded hepatitis and jaundice.[16] Vitamin E (alpha tocopherol) is also a nutritional antioxidant that protects against different routes of membrane peroxidation. It is not known if vitamin E is deficient in liver diseases, and no systematic evaluations of the effect of supplementation in such diseases exist. It is a lipid-soluble vitamin so, theoretically, it is expected to be helpful in cholestatic diseases. Excess of vitamin E has no side effects.

226.2.6 S-Adenosyl-L-methionine

SAMe is a natural metabolite in the hepatocytes. It is a precursor for cysteine, which is one of the amino acids of GSH. GSH forms one of the main defense mechanisms of the cell against intoxications, and depletion causes oxidative stress. Depletion might occur by exhaustion due to exposure to toxic substances. SAMe is important in the defense against free oxygen radicals.[12–14] The precursor of SAMe is methionine, which is activated by SAMe-synthetase. Theoretically, deficient capacity of this liver enzyme as a consequence of liver disease could cause inadequate production of SAMe and GSH. SAMe is nontoxic, and administration of

exogenous SAMe could restore deficient GSH in the hepatocytes. One report[17] exists of GSH levels in the liver of naturally occurring liver diseases of dogs and cats. This report showed greater variation (both decreased and increased) of GSH levels in disease than in health, which makes it difficult to conclude that low levels are a critical factor in the pathogenesis of such liver diseases. No evidence-based reports are available of clinical trials on the effect of SAMe treatment.

226.2.7 Silymarin

Silymarin or silibilin is the active component extracted from the fruit of *Silybum marianum,* milk thistle. Silymarin has been used for centuries in human medicine as treatment for liver diseases. It appears to be a strong free-radical scavenger by increasing cellular SOD. Many reports exist concerning its protective and even life-saving actions on the liver after intoxications with the mushroom toxin phalloidine[9–18] or acetaminophen, both of which exert their toxic effects by oxidation. Both experimentally and in human clinical medicine it appears very effective against these toxins. The typical oxidative changes of the mitochondria can be prevented in experimental intoxications with mushroom toxins, and this leaves no doubt about the therapeutic potential of silymarin. Treated dogs had lower liver enzymes, reduced prolongation of prothrombin times, and survived in one trial, whereas one third of the placebo-treated dogs died.[9] It is not known how long after intoxication silymarin has beneficial effects; reports vary from 10 minutes[9] to 5 hours.[18] This may also depend on the amount of toxin and the effective dose of the milk thistle extract. No studies have compared the protective effect of silymarin with other antioxidants such as vitamin E, SAMe, or N-acetyl-cysteine.[10]

No evidence proves that antioxidants have a beneficial effect in liver diseases not primarily caused by oxidative damage. For intoxications with phalloidine or acetaminophen, both silymarin and SAMe proved to be protective in experimental rodent studies and dogs; however, no comparison exists that is most effective. For liver diseases caused by congenital copper storage diseases, antioxidant therapy may be additional to chelating drugs. A beneficial effect has only been proven in LEG rats with Wilson's disease,[16] and no studies have shown that combining chelating drugs with vitamin yields better results than chelation alone.

226.2.8 Antifibrotic Drugs

Fibrosis is the unavoidable sequel of chronic liver disease, and untreated or untreatable chronic liver diseases end in fibrosis, cirrhosis, and incapacity of the liver to regenerate. Increased lipid peroxidation in hepatocytes activates the mesenchymal hepatic stellate cells (HSCs). Transforming growth factor beta-1 (TGF-β) is the principle and most potent fibrogenic cytokine and is produced by Kupffer cells and HSCs.[19,20] HSCs are also the primary target cells that produce extracellular collagen matrix.[21] Specific drugs to inhibit TGF-β[20] are not clinically available. Hepatocyte growth factor (HGF) is the principle hepatotrophic factor for liver regeneration, and it suppresses hepatic fibrogenesis in animal experiments. Inhibitors of HSC also exist.[19,20] These three most promising routes (inhibition of TGF-β, inhibition of HSC, and stimulation of HGF) to actively reduce liver fibrosis and stimulate liver regeneration are not beyond the experimental stage. Presently the reduction of lipid peroxidation (which reduces HSC activation) is the only clinically available method. Silymarin, SAMe, and vitamin E are most promising in this respect, but no clinical studies exist. One certain way to stop fibrogenesis of the liver to prevent cirrhosis is to treat the underlying disease and thereby stop progression of fibrosis. This is certainly an explanation of why drugs such as prednisolone, azathioprine, penicillamine, zinc, and vitamin E have been mentioned as having antifibrotic effects.

Colchicine is the only drug used specifically to stop and reduce fibrosis. It is thought to act via stimulation of collagenase activity. The disadvantage is that side effects have been reported, such as vomiting, diarrhea, and neurologic signs but side effects are rare. Neither in human medicine nor in veterinary medicine has the clinical effect been proven. In large clinical studies in humans, no effect was shown[22,23]; in veterinary medicine only several anecdotal reports exist in which colchicine was always part of multidrug therapy. No reports exist concerning the use of colchicine to treat liver diseases in cats. The use of colchicine in veterinary medicine should be postponed until it has been firmly proven effective.

226.2.9 Anticopper Medications

One cause for chronic hepatitis which is rare in humans but may be much more important in dogs is storage of copper in the liver, which can induce oxidative damage due to free intracellular copper. Copper toxicosis in Bedlington terriers has been the historical example of this form of chronic hepatitis that is caused by a deletion in the Murrl gene.[24] A number of forms of chronic hepatitis exist in different breeds that have been attributed to copper storage as the causative factor. These breeds are Bedlington terriers,[24] Skye terriers,[25] Dalmatians,[26] West Highland white terriers,[27] and Turkish shepherds.[28] Copper may also accumulate as a result of impaired biliary excretion secondary to cholestatic diseases. Thus hepatitis in Dobermans and Labrador retrievers may be a primary copper metabolic disease or secondary copper accumulation due to intrahepatic cholestasis in the course of hepatitis.[29] The increasing list of diseases in which hepatic copper accumulation may be the primary cause, indicates that specific therapies aimed at reducing free copper in the liver may become more important. Excessive copper is generally stored and encapsulated in the hepatocyte lysosomes, and cannot be reached by chelating drugs. Because it is the free cytoplasmatic (and not the lysosomal copper) that causes oxidative damage, quantitative copper measurement does not necessarily reflect the success of chelating or other therapy. Only diseases in which copper accumulation is the primary defect need specific anticopper medication. If copper accumulates as the consequence of a cholestatic disease, specific treatment of the underlying disease will reduce the amount of free cellular copper. The rationale for additional chelating medication has never been proven for such diseases. Chelating drugs should be used with some care because dogs treated for long periods with chelators can develop copper deficiency.

1437 1438

Three forms of anticopper medications are available for treatment of primary copper storage diseases. First, chelating drugs can actively bind free extracellular copper, upon which the complex is excreted into the urine by the kidneys. Extracellular copper exchanges with free intracellular copper so that by constant exhaustion of the extracellular copper pool, the toxic intracellular excess is also removed. At present two copper chelators are available. D-penicillamine has been the first drug successfully used to treat humans with Wilson's disease, and it has also been widely used to treat Bedlington terriers with copper toxicosis.[30,31] The author's experience in about 100 Bedlington terriers diagnosed at 1 year of age is that medication with penicillamine from young age on prevents the development of hepatitis and clinical signs. This was, however, not tested in a double-blind, placebo-controlled, and randomized study. The alternative copper chelating drugs are 2,2,2-and 2-3-2-tetramine tetrahydrochloride.[32] The 2-3-2-tetramine form gives higher cupriuresis in healthy dogs, and it has been used in one clinical study. However, only the 2,2,2-tetramine form (Trientene) is commercially available. Trientene may be more efficient in copper chelation than penicillamine, because copper deficiency as a result of chronic use has only been reported for Trientene.[31] The advised dose for both chelators is identical: 10 to 15 mg/kg twice daily. The effect of Trientene in copper storage diseases has only been mentioned anecdotally. It is therefore difficult to advise that it is the most appropriate copper chelating drug for dogs. Based on the facts that much more experience exists with D-penicillamine in dogs, and that it

remains the preferred drug for humans with Wilson's disease, the author's preference is to use D-penicillamine. Penicillamine may have infrequent side effects, mainly nausea and vomiting. It is therefore preferred to give it twice daily together with meals. This is also the best time of administration because the blood levels will be highest at the time alimentary copper is absorbed. A second anticopper medication is zinc[33] gluconate or acetate in capsules for oral use (10 mg elemental zinc/kg twice a day). In the intestinal tract, zinc induces metallothionein in the enterocytes. This protein binds copper, and the complex is sequestered with the senescent enterocyte into the intestinal lumen. Unlike chelating drugs, zinc salts should be given 1 hour before each meal, so induction of metallothionein has taken place when alimentary copper is absorbed. Combinations of chelators and zinc salts should be avoided, because when the chelator binds zinc the removal of copper becomes less effective. The positive effect of zinc therapy has been evaluated critically in humans and has been reported anecdotally in dogs with copper storage disease. The indications for zinc therapy and chelating drugs are different. Chelators bind free copper actively and thus are an effective way to quickly remove the free intracellular copper that causes the hepatic damage. Copper chelators should be used as a routine for about 3 months to achieve complete inactivity of the hepatitis. Zinc should be used as a preventive drug to avoid accumulation of free copper in the liver. It is therefore especially effective when given to young dogs in which copper storage has been diagnosed but in which no hepatitis is present yet. This was usually done by copper measurement in liver biopsies of Bedlington terriers when they were 1 year old. At that age copper accumulation is sufficient to be diagnostic but not yet enough to produce hepatitis. The author's clinic has treated about 70 young Bedlington terriers with subclinical copper toxicosis life-long with zinc gluconate (clinical disease has been prevented in all cases). Presently, DNA tests can be performed at young age so that liver biopsies can be avoided. It is also possible to treat dogs with clinical disease due to copper excess for several months with D-penicillamine; when liver biopsies prove recovery from hepatitis, renewed accumulation can be prevented with life-long zinc medication. Zinc gluconate has side effects other than transient inappetence in rare cases. Very long treatment can induce copper deficiency.[32] It is cheap and therefore the preferred form of treatment to prevent copper-associated hepatitis. When higher than the recommended doses are given very long, zinc intoxication can cause hemolytic anemia. The third potential form of medication for copper storage diseases is through antioxidants. It is more logical to treat the cause by removing copper by chelation rather than to fight the effects. However, in rare cases in which excessive copper causes hemolytic crisis,[34] it may be advisable to combine chelating drugs and antioxidants such as SAMe, silymarin, or vitamin E.

226.2.10 Treatment of Ascites in Chronic Liver Disease

Ascites typically is a late sign of decompensation in the course of chronic liver diseases, such as chronic hepatitis, cirrhosis, and portal vein hypoplasia in dogs. Cats very rarely have ascites due to chronic liver disease. The portal blood pressure is only high enough to cause ascites without hypoalbuminemia in cases of acute complete obstruction of the portal vein by thrombosis and congenital arteriovenous fistulas. Whatever the cause, in all liver diseases associated with ascites the high portal pressure may also lead to formation of portosystemic collateral vessels and various grades of hepatic encephalopathy (HE). The potential risk for HE brings the need to use diuretics with caution.[35] The main complicating factors by which HE may induce coma that may be lethal are alkalosis and hypokalemia. Only the nonionized NH_3 form of ammonia penetrates cellular (neuronal) membranes. In any form of alkalosis the reaction equilibrium: $NH_3+H^+ \times NH_4^+$ shifts to the left. Therefore ammonia is much more toxic in alkalosis. In case of hypokalemia the plasma potassium is replenished by shift of potassium from the cells, in exchange with sodium and hydrogen ions. The resulting hydrogen shift causes alkalosis in the extracellular fluid and acidosis in the cells so that ammonia can easily penetrate cells. Intracellularly it becomes ionized in which form it cannot leave the cell. Blood ammonia,

which is the best parameter to monitor HE, may then be surprisingly low in relation to the severity HE because most of it is trapped inside the cells. This cellular ammonia trap is easily activated with the use of most diuretics. It is therefore better to use potassium-sparing aldosterone receptor antagonizing diuretics, such as spironolactone (2 to 4 mg/kg twice a day). Only if the dog eats well enough to have adequate supply of alimentary potassium to substitute the renal loss can loop diuretics be used. Combinations of furosemide and spironolactone may be very effective to treat ascites. It is important to monitor blood pH and potassium and to correct potassium deficiency.

In a relatively short period of several days or weeks, the abdominal accumulation of free fluid can account for more fluid than the entire circulating volume. In this period the renin-angiotensin-aldosterone system is highly activated, resulting in sodium and water retention and potassium loss. Intravenous fluid therapy and potassium compensation is necessary when the dog does not eat or drink sufficiently. Complete paracentesis of ascetic fluid may complicate HE and should be avoided in liver patients.

Chronic hepatitis and even cirrhosis with active inflammation may improve so much upon treatment with corticosteroids that the disappearance of the inflammatory infiltrates provides enough reduction of portal pressures to induce remission of ascites. A low-sodium diet may help to keep the ascites controlled. 1438 1439

226.2.11 Treatment of Hepatic Encephalopathy

The source of the known toxins causing brain neurotransmitter changes known as *HE* is protein digestion in the intestinal tract. Ammonia and aromatic amino acids are the two main factors.[35] Both require portosystemic collateral circulation, either congenital or acquired due to chronic portal hypertension, to reach the systemic circulation and the blood-brain barrier. The reserve capacity of the liver in dogs is enough to prevent HE in liver disease without collateral circulation. Cats do not make the essential amino acid arginine, and HE may occur without shunting as a result of fasting. Arginine is an essential intermediate of the hepatic urea cycle, and deficiency causes inadequate detoxification of ammonia. These cats often develop hepatic lipidosis simultaneously. Lipidosis and HE are a manifestation of their inability to synthesize several essential amino acids. Large variations in susceptibility to these effects exist between cats.

Management of HE is different for dogs and cats with congenital or acquired portosystemic shunting and cats with HE due to fasting hyperammonemia resulting from arginine deficiency. Portosystemic encephalopathy, which is by far the most common form, should be treated with an appropriate diet of reduced protein content with specific reduction of sources of aromatic amino acids. Very strict reduction of proteins may be counterproductive; dog studies have shown that prevention of catabolism (i.e., negative energy balance) is more important than strict maintenance of low-protein intake. Another important factor is that lactulose and soluble fiber in the diet helps to reduce ammonia uptake from the large intestines. Lactulose and soluble fibers have many effects on ammonia metabolism; the most important effect is that it is metabolized by the colonic bacterial flora to produce acids that reduce the pH of colonic content. Ammonia is then present in the ionic form that is not absorbed and thus lost with the feces. Well-balanced commercial liver-support diets are available that meet these requirements of adequate energy content, sufficient reduction of protein with special emphasis on aromatic amino acids, and presence of soluble fiber. These diets are also low in copper and sodium. Sodium reduction may be important if portal hypertension is present, because in these cases not only HE but also ascites may form with interrelated metabolic complications as described previously. Low copper is not necessary in relation with HE or ascites, but is important in the management of those forms of canine hepatitis that are thought to be caused by copper metabolic diseases.

If diet alone is not sufficient to manage cases with portosystemic encephalopathy, clinicians can improve the HE status by giving oral lactulose. Lactulose was developed to treat constipation, because the disaccharide molecule is metabolized in the colon into multiple smaller molecules that increase the osmotic content of the colon and attracts water into the feces. The best guideline for use of lactulose for management of HE is to give just enough (twice daily) to reach slightly softer stool. The combination of diet and lactulose is often sufficient to manage chronic HE for many years in cases in which the underlying cause cannot be treated (inoperable portosystemic shunts, arteriovenous fistula, portal vein hypoplasia, inactive cirrhosis).

Deterioration of HE may occur due to several instances (see Ascites), the most important being catabolism, dehydration, alkalosis, hypokalemia, and formation of ascites. Sudden high intestinal ammonia production in the face of portosystemic collateral circulation may also cause sudden aggravation of HE. This may be caused by intestinal bleeding from gastroduodenal ulcers, which may be associated with chronic liver diseases. Blood is the most ammoniagenic protein, and in sudden deterioration it may be important to examine and treat possible gastrointestinal (GI) bleeding. Furthermore, key rules to control HE are measurement of blood pH, potassium, and ammonia, correction of hypokalemia, correction of hypovolemia, and intravenous feeding to correct catabolism. It should be understood (see Ascites) that the blood level of ammonia and potassium are reflections but not exact representations of what is going on in the neurons.

One factor in the pathogenesis of HE is an increased activity of the neuronal GABA/benzodiazepine receptor system, which suppresses neuronal activity. For this reason, one should be extremely careful in using any sedation or anesthesia exploiting this receptor system. If necessary, inhalation anesthesia is safest, because it exploits different receptors and does not depend on liver function.

Finally, additional measures exist with beneficial effects that have never been proven in veterinary cases. One of them is the use of antibiotics such as neomycin to eradicate or change the intestinal flora. In humans, lactulose and neomycin can have synergistic effects. Neomycin may be an option to use as an enema in combination with lactulose in rare cases of HE crisis.

226.2.12 Hepatic Encephalopathy and Liver Lipidosis in Cats

Cats can have portosystemic encephalopathy just like dogs and humans. However, the cats, which are susceptible to develop liver lipidosis when fasting, are also prone to develop HE due to deranged metabolism. Having a shared metabolic basis, feline hepatic lipidosis and nonportosystemic HE require essentially the same therapy. With this understanding, the general rules concerning the influence of hypokalemia and alkalosis also apply to HE in cats.

Hepatic lipidosis in cats is essentially a consequence of catabolism from anorexia due to any cause. Lipidosis can develop within a few days but may also take 2 weeks to occur. Some cats can withstand prolonged fasting without developing clinically significant lipidosis at all. The precise pathogenesis of lipidosis is not known in detail, but catabolism leads to decreased insulin-to-glucagon ratio in the circulation, which stimulates hormone-sensitive lipase to release fatty acids. The liver is the main place for their metabolism. One of the principle routes by which the liver can make fat stores suitable for use in other tissues is by the formation of very low–density lipoproteins (VLDL). One of the essences of this complex metabolic disorder is the unavailability of essential amino acids. These are necessary for different liver functions, such as formation of apoproteins for composition of VLDL in which form accumulating triglycerides can be exported from the liver cells, and the urea cycle in which arginine is essential. For treatment of both HE and lipidosis it is therefore essential to restore the energy balance especially by giving proteins. High-energy diets containing predominantly fats or sugars do not help these cats. Feeding liquefied baby food or commercial high-energy

and high-protein veterinary formulations are equally good. The goal is to restore the energy balance and supplement amino acid deficiencies, especially arginine and taurine. L-carnitine may be an important factor because it may help the hepatocytes to exploit fatty acids in beta oxidation.[36] This is the only form of HE requiring high-instead of low-protein feeding. A daily caloric intake around 75 kcal/kg is adequate. The supplementation of vitamins by multivitamins may be beneficial in cats with long-term anorexia. When the cat is not yet too ill, a dedicated owner can often force-feed with a syringe. Otherwise a gastrotomy tube is most appropriate for long-term force-feeding without stress for the cat.[37] Force-feeding is often required for several weeks until the cat starts eating spontaneously. It is dangerous to stimulate appetite by diazepam administration. The risk for HE is a contraindication for drugs activating the GABA/benzodiazepine receptor system, over stimulation of which is part of the pathogenesis of HE. Cats with hepatic lipidosis can easily develop insulin resistance with hyperglycemia, which may gradually increase to glucose levels as seen in diabetes mellitus. The insulin resistance implies that very large doses of insulin would be needed, with the inherent risk for sudden hypoglycemia. A benefit of treatment with insulin has never been demonstrated, and it is advised to restrict therapy to forced feeding.

1439 1440

Glucocorticoids are contraindicated because they stimulate lipolysis and fatty acid accumulation in the liver, induce catabolism, and increase the risk for hyperglycemia. Some authors advocate the use of antibiotics for cats with hepatic lipidosis, but a positive effect has never been proven. In the author's clinic, antibiotics are not given as a routine.

It is essential to try to identify the primary cause of anorexia. Not eating is very nonspecific and occurs for multiple reasons. It is often impossible to find an underlying disease. The reader should note that this may also be a primary liver disease[38] that may remain undiscovered when the diagnosis of lipidosis is based on thin needle aspirates of the liver. Neutrophilic or lymphocytic cholangitis and hepatic lymphosarcoma are the most frequent hepatobiliary diseases causing lipidosis. Finally, it is important to realize that some cats are metabolically predisposed to develop lipidosis and nonportosystemic HE, whereas other cats can withstand negative energy balance reasonably well. The predisposed cats will easily develop the same syndrome later in their lives, and it is important that owners understand this risk. Successful management is primarily dependent on early recognition of these metabolic disorders.

226.2.13 Dietary Therapies for Liver Disease

The most important requirements for dietary management of liver diseases have already been mentioned under ascites, HE, and feline hepatic lipidosis. Only the copper content of dog food requires an additional remark. Several copper-associated forms of chronic hepatitis exist in dogs. With careful evaluation of the causes of hepatitis in different breeds, clinicians may discover more forms of hepatitis in which abnormal copper metabolism is the primary problem. The goal is not only to treat these cases successfully with chelating and other drugs but also to prevent disease. This may at least in part be achieved by feeding a low-copper diet. It is very difficult to formulate a home-cooked diet containing very low copper. A realistic alternative is to use one of the commercial liver diets that contain much lower copper than regular diets.

226.3 PARENCHYMAL LIVER DISEASES

Parenchymal liver diseases may be divided into metabolic diseases affecting the liver (such as steroid hepatopathy, lipidosis of the liver in case of diabetes, or induced by catabolism in fasting cats), systemic diseases secondarily involving the liver (hypoxic necrosis of the liver, nonspecific reactive hepatitis due to endotoxemia), primary hepatitis (chronic or acute) of toxic, viral or unknown cause, copper storage diseases with secondary

hepatitis, and the end-stage of each form of chronic hepatitis: cirrhosis. Many of the metabolic diseases and the diseases in which the liver is secondarily involved do not require specific treatment. The regenerative capacity of the liver will result in spontaneous recovery upon successful treatment of the underlying disease. Parenchymal liver diseases that need specific treatment are acute and chronic hepatitis (including lobular dissecting hepatitis) and copper-associated hepatitis in dogs, cirrhosis in dogs, hepatic abscesses in dogs, and hepatic lipidosis in cats.

226.4 HEPATITIS IN DOGS

226.4.1 Acute Idiopathic Hepatitis

The cause of hepatitis is not known in most cases. Viruses may be the cause of acute idiopathic hepatitis in dogs in analogy to many other species. This implies that treatments with immunosuppressive drugs (prednisolone, azathioprine) that are being used for chronic hepatitis are contraindicated for acute hepatitis in which there may be florid viral infection. Most cases of acute hepatitis recover spontaneously and need only supportive care with antiemetics and fluid therapy. Oxidative intracellular damage may in theory be part of the pathogenesis of many liver diseases, including acute and chronic hepatitis. However, a positive effect of antioxidants has never been shown in acute idiopathic hepatitis. Acute hepatitis in dogs is almost never caused by bacterial infection. Therefore treating with antibiotics is not needed. In acute hepatitis the liver reserve capacity is almost never exhausted, so prevention of sepsis resulting from insufficient liver function by antibiotic medication is also not necessary. As a routine, idiopathic acute hepatitis, which is a histopathologic diagnosis, does not need specific treatment. Supportive care may be indicated: antiemetics in case of severe vomiting and fluid therapy in case of dehydration. The most important point in making the diagnosis of acute idiopathic hepatitis is that the disease may progress into chronic hepatitis. Usually recovery takes place in about 3 weeks. In a small number of cases, the author has seen acute hepatitis become chronic. This usually begins as a subclinical chronic hepatitis without clinical signs and is often unnoticeable with blood examination. It is therefore recommended to take a control biopsy 4 to 5 weeks after the diagnosis of acute idiopathic hepatitis so that the onset of chronic hepatitis can be discovered in an early phase. Beginning forms of chronic hepatitis can be treated very successfully with prednisolone (5 to 6 weeks 1 mg/kg/day, divided over two doses), preventing advanced fibrosis or cirrhosis. Untreated cases will become clinical in the very chronic stage, which is about 4 to 8 months later. In that stage it is usually not possible to achieve complete recovery of fibrotic damage.

226.4.2 Hepatitis and Necrosis Due to Phalloidine or Acetaminophen Intoxication

It is important to ask the owner if acetaminophen or mushroom toxins (phalloidine) may have been ingested recently. These toxic forms of hepatitis are caused by oxidative damage and require specific treatment. Phalloidine intoxication should be treated with silymarin (50 mg/kg/day) for 3 to 5 days. The success depends on early recognition and immediate therapy. Silymarin has been reported to lose its effect when given a few hours after intoxication. Any other antioxidant therapy such as SAMe should also be useful, but reports have focused on silymarin.[9] Supportive care, induction of vomiting in very acute intoxication, and measures to prevent or reduce HE are also indicated. Many dogs die within 1 week due to liver and kidney failure. Acetaminophen intoxication should be treated similar to phalloidine intoxication. Several reports exist concerning the favorable effect of SAMe treatment[12–14] for acetaminophen intoxication (800 mg/kg/day), but the classical treatment is with the combination of N-acetylcysteine[10] (140 mg/kg orally, every 6 hours during 3 days), vitamin C (25 to 35 mg/kg orally, every 6 hours for 2 days), and cimetidine 5 mg/kg twice a day for 4 days. Historically, acetaminophen and phalloidine intoxication have different treatments, but it is logical to

expect good effect of both silymarin and SAMe, in conjunction with symptomatic therapy. Dogs with acetaminophen intoxication may have hemolysis and blood transfusion may be required.

226.4.3 Leptospirosis

Leptospirosis is an acute disease, primarily of the kidneys, but it also causes a nonspecific reactive hepatitis with intrahepatic cholestasis. Icterus is therefore common, although the symptoms arise mainly from acute nephritis.[39–40] Each dog with acute disease displaying icterus and acute renal failure should be treated immediately with ampicillin or amoxicillin and clavulanate.[40,41] Early institution of antibiotic therapy may be life saving. If the diagnosis is confirmed by high immunoglobulin M (IgM) titers, antibiotics are continued until kidney function is restored. Then latent bacteria in tubular epithelial cells that may cause leptospiruria should be eradicated with streptomycin given for 2 consecutive days. The acute renal failure should also be treated with fluid therapy.

226.4.4 Liver Abscess

Liver abscesses are rare in dogs and cats. Treatment is by surgical removal after pretreatment with antibiotics. The choice for specific antibiotics should be based on culture of an ultrasound-guided thin needle aspirate. *Staphylococcus* and *Clostridium* are most common. Antibiotics should be administered long-term, (6 to 8 weeks). Hepatic abscesses occur predominantly in older dogs, and in the author's experience many cases have a liver cell carcinoma with central necrosis that became secondarily infected. This can easily be missed; therefore clinicians should also take histologic biopsies from the margins of the abscess.

226.4.5 Chronic Idiopathic Hepatitis

Chronic hepatitis is one of the most frequent liver diseases in dogs. In most cases it is not possible to indicate a cause (idiopathic hepatitis). The inflammatory cells are lymphocytes and plasma cells, indicating that at least part of the pathogenesis may be immune-mediated. The only well-documented therapy is with glucocorticoids. Prednisolone should be given until the inflammation (liver cell necrosis and infiltration with inflammatory cells) has recovered completely.[1] This cannot be concluded based on clinical signs or blood examination because both will be influenced by the glucocorticoid treatment. Therefore the only reliable way to evaluate the result is with repeated liver biopsies. It is usually possible to predict approximately how long the medication should be continued. High activity (necrosis of hepatocytes and presence of inflammatory cells) of the inflammation and high degree of fibrosis indicate the need for longer treatment than in cases of low active inflammation with little fibrosis. As a rule, chronic hepatitis should be treated for at least 6 weeks; severe cases require longer treatment up to 10 to 12 weeks. Dose regimens vary. Our routine is to use a continuous dose of 1 mg/kg/day, divided over two daily doses. In the author's experience, lower doses (0.5 mg/kg/day), medication on alternating days, or both is often less effective to achieve complete remission of the disease. If unacceptable side effects indicate the need to decrease the prednisolone, combination therapy with azathioprine can be given (both drugs 0.5 mg/kg/day).

Complete remission of the disease occurs in most of the cases. Fibrotic changes are usually permanent. When inflammation disappears the dogs are usually symptomless. Severe fibrosis or cirrhosis may require life-long support by dietary measures and lactulose.

226.4.6 Copper-Associated Hepatitis

Copper-associated forms of hepatitis occur in Bedlington terriers, West Highland white terriers, Skye terriers, Dalmatian dogs, and Turkish shepherds. If active hepatitis is found, treatment should be with copper chelating drugs such as penicillamine. Prevention of clinical disease in cases diagnosed early or maintenance therapy with chelation when the inflammation has stopped can be achieved with zinc salts. Details are given in the general section of this chapter. Dobermans, especially 5 to 7 years old females, may display a specific form of hepatitis, called *Doberman hepatitis*. The prognosis of this disease has generally been reported to be bad, and in the author's clinic almost all Dobermans with this disease die on the usual medications. In the author's clinic, Doberman hepatitis has been treated with penicillamine alone, and this has resulted in complete remission of the disease. This may be regarded as support for the hypothesis that copper storage plays a causative role in this disease. Double blind, placebo-controlled, randomized studies are needed.

226.4.7 Lobular Dissecting Hepatitis

This is a very severe form of hepatitis that develops rapidly and is usually lethal within 2 to 4 weeks. Extremely pronounced fibrosis occurs, which is the reason that despite the acute course, this disease is classified under the chronic forms of hepatitis. The disease occurs more in younger dogs and affects all breeds and both sexes. Medication with immunosuppressive drugs is usually without success. No reports exist on successful medical treatment for this disease. Treatment with colchicine[22,23] is appropriate for this disease.

226.5 DISEASES OF THE BILIARY SYSTEM

226.5.1 Destructive Cholangiolitis in Dogs

This is strictly not a form of hepatitis but an idiosyncratic reaction in dogs, nearly always to drugs containing sulfonamides. Necrosis of the smaller intrahepatic bile ductules is the result, and these dogs display extremely severe intrahepatic cholestasis. The first action is immediate withdrawal of the sulfonamide medication. The necrosis of the intrahepatic bile ductules is irreversible, and the only hope is that it is possible to save and exploit the remaining biliary system. In the author's experience, it is essential to start treatment with UDCA immediately. As a rule, life-long medication is needed to exploit the remaining biliary system optimally. When the dog shows enough response to justify hope for a long-term survival, the clinician should evaluate the long-term reaction in the liver. Chronic cholestasis may induce a chronic damage to the liver with continuous loss of functional hepatocytes and activation of the deposition of fibrous tissue. This may finally produce portoportal bridging fibrosis in the liver (biliary fibrosis) that, although the architecture of the liver lobules remains in tact, can give rise to portal hypertension. Ascites and formation of acquired portosystemic shunting may result. Long-term progress can often be predicted by evaluating liver biopsies 2 to 3 months after the start of treatment. If enough capacity of the intrahepatic biliary system remains, some dogs may be maintained with continuous ursodeoxycholic acid medication. In decompensating cases, supportive treatment or prevention of HE or ascites is indicated.

226.5.2 Neutrophilic Cholangitis in Cats

This disease is characterized by a neutrophilic inflammation of the biliary tract. The synonym is suppurative or acute cholangitis. This is essentially a septic disease, and it is therefore required to sample bile from the gall bladder by ultrasound-guided puncture with a thin needle for cytologic evaluation and both aerobic and

anaerobic culture with sensitivity testing. In the vast majority of cases *E. coli* is cultured, but *Staphylococci* or other bacteria may also be identified. It may in some cases be an infection superimposed on pre-existing bile duct obstruction associated with cholelithiasis, pancreatic, or intestinal disease.[42] Bile duct obstruction 1441
requires surgical decompression and antibiotic medication guided by culture of bile. The true uncomplicated 1442
neutrophilic cholangitis is an acute disease characterized only by bacterial infection of the bile ducts, as evaluated with the combination of bile culture, liver histology, and ultrasonography. Uncomplicated neutrophilic cholangitis responds quickly to antibiotic therapy. Amoxicillin-clavulanate, amoxicillin, or ampicillin may be the first choice treatment until the results of culture become available. Treatment for at least 4 weeks is necessary. If pre-existing bile duct disease is present, the treatment should be adjusted accordingly. The additional use of UDCA is often advised, but in the author's experience single antibiotic therapy is adequate in nearly all uncomplicated cases.

226.5.3 Lymphocytic Cholangitis in Cats

This is a very chronic disease of the bile ducts (both intra-and extrahepatic). Secondary inflammation with fibrosis may also affect the portal tracts. Both in the bile system and in the portal tracts, lymphocytes are the predominant inflammatory cell type. Because the principle site of the disease is the bile system and not the liver, the standardized name is *lymphocytic cholangitis* (synonyms cholangiohepatitis, chronic or lymphoplasmacytic or nonsuppurative cholangitis, sclerosing cholangitis). The cause is unknown, but a similar form of chronic cholangitis may be due to liver fluke infestation, which occurs on all continents. The very chronic bile duct inflammation of lymphocytic cholangitis causes irregularly distended, fibrotic bile ducts that are prone to secondary bacterial infection. The wide, irregular, but still more or less patent bile ducts that are visible on ultrasonography, should be distinguished from distension due to extrahepatic bile duct obstruction. In case of obstruction, treatment with UDCA is contraindicated,[4] whereas it is one of the most useful medications for lymphocytic cholangitis. In most cases the difference can only be made with histologic examination of a liver biopsy. The two diseases have different histological characteristics. Liver fluke eggs may also be visible histologically in the bile ducts, but they should also be evaluated with fecal examination.

Agreement on treatment of lymphocytic cholangitis is not yet settled. Similarities exist (with human primary sclerosing cholangitis and primary biliary cirrhosis) for which the pathogenesis is equally unknown but has been proposed to be autoimmune. This has prompted treatment of these cats with glucocorticoids (2 to 4 mg/kg/day). However, this has been found to be ineffective in most cases.[42] As confirmed by the author's experience, any response to even very long-term high-dose glucocorticoid medication is rare. Alternatively, methotrexate in addition to glucocorticoids has been proposed,[42] because this is used for human autoimmune disorders. However, this treatment is not without risk, and a positive effect has not yet been reported. Similarly, metronidazole may have an effect on cell-mediated immunity, and it has been advocated in combination with glucocorticoids. However, no reports are available on the evaluation of this combination.

UDCA may be the only generally advised drug for which at least a theoretic basis exists. It has beneficial effects on cholestatic diseases in different ways. Positive effects on nonobstructive cholestatic disease have been proven in human cholestatic diseases. UDCA (15 mg/kg/day, divided over two doses) is advised as the main therapy for this disease. Treatment should be given until the disease has resolved, which in many cats implies life-long medication. No adverse effects of this therapy have been reported in dogs or cats. It is imperative to exclude extrahepatic bile duct obstruction before starting UDCA medication.

Antibiotics may have a place in the treatment of cats with lymphocytic cholangitis, but no reports exist concerning the effect of chronic antibiotic medication. It is not logical to treat all cats with antibiotics. The bile culture (aerobic and anaerobic) is positive in some cats, presumably due to secondary infection of the

abnormal biliary system. It is advised to perform gall bladder puncture to obtain bile for culture and cytologic examination in all cats with cholangitis. Cats with a positive culture require antibiotics, based on the sensitivity tests. Long-term treatment is needed (6 to 8 weeks). At present, one should accept that the cause and pathogenesis of lymphocytic cholangitis is unknown, and that therapy is in most cases does not induce remission. Clinical improvement and slackening of the progression may occur.

If liver fluke infestation is present or suspected based on liver histology, the preferred treatment is with praziquantel (Droncit). Medication for 3 days (20 mg/kg/day) is most commonly given, but reinfections may occur. It is important to evaluate feces for fluke eggs after medication.

227 CHAPTER • 227 Inflammatory Canine Hepatic Disease

Michael D. Willard

227.1 CHRONIC HEPATITIS

Chronic hepatitis (CH) refers to a syndrome that has previously been identified by several names (e.g., chronic active hepatitis, chronic persistent hepatitis, chronic lobar hepatitis). In this chapter, *CH* will refer to chronic (i.e., ε6 months) canine hepatic disease in which a hepatocellular necrosis exists that is associated with a predominately lymphoplasmacytic inflammation that typically progresses to fibrosis and cirrhosis. The cause, if known, should be included as an adjective (e.g., drug-induced CH, copper-associated CH); otherwise the CH is termed *idiopathic*. Additional descriptors (i.e., mild, moderate, severe) of the severity of the inflammation and of the chronicity as indicated by fibrosis are desirable.[1–3]

CH may have various causes (e.g., copper, drugs, infectious agents), and familial tendencies exist. Breeds that have been reported to have an increased frequency of CH include Doberman pinschers, Bedlington terriers, West Highland white terriers, Cocker spaniels, dalmatians, Skye terriers, standard poodles, Labrador retrievers, German shepherd dogs, Scottish terriers, and beagles.[1,2,4,5] Dogs 4 to 7 years old seem more commonly affected. Some papers suggest that females are more commonly affected, whereas others suggest that both sexes are at risk. However, particular breeds have definite sex predilections (e.g., female Doberman pinschers, male cocker spaniels).[1–3]

Most dogs with CH have idiopathic disease, and immune mechanisms may play an important role in some animals.[2,3] In one recent study, CD3+ lymphocytes were the most common lymphoid cells in the liver of 16 dogs with CH. The number of CD3+ cells was positively correlated with necrosis, and these lymphoid cells occasionally surrounded degenerating hepatocytes. Inflammation was worse in the earlier stages but then decreased as the livers became cirrhotic.[6] Whether this immune response was the cause of or an effect of the hepatitis remains to be elucidated. This is in keeping with another report that found that 54% of the hepatic lymphocytes in normal dogs were CD3+ cells.[7] Antinuclear antibodies and antibodies to liver membrane proteins have also been found in some dogs with CH, but again, cause and effect has not been clarified.[1,2]

Copper accumulation has been associated with CH in several breeds (Box 227-1). In Bedlington terriers, hepatic copper accumulation is the cause of the hepatitis; however, copper may accumulate secondary to cholestasis. In most other breeds the relationship between copper and CH is either uncertain or the copper accumulation is thought to be an epiphenomenon. Excessive hepatic copper accumulation secondary to hepatitis may be clinically insignificant, but hypothetically it might be able to further aggravate hepatic injury. Normal dogs generally have less than or equal to 400 µg copper/gm hepatic tissue, dry weight (i.e., parts per million [ppm]).[8] Dogs with greater than 2000 ppm usually have hepatic disease caused by copper, although one author stated that dogs may have 3500 ppm before hepatic disease occurs.[9] In dogs with hepatic disease, hepatic copper levels less than 1000 ppm are probably secondary to hepatic disease, concentrations greater than 2000 ppm are probably primary causes of hepatic disease, and concentrations greater than 1000 ppm are possibly primary causes.[8,10]

227.1.1 **Box • 227-1 Breeds That Have Been Associated with Increased Hepatic Copper Concentrations**

Bedlington terrier

Airedale terrier

Bull terrier

Bulldog

Cocker spaniel

Collie

Dachshund

Dalmatian

Doberman pinscher

German shepherd dog

Golden retriever

Keeshond

Kerry blue terrier

Labrador retriever

Norwich terrier

Old English sheepdog

Pekingese

Poodle

Samoyed

Schnauzer

Skye terrier

West Highland white terrier

Wire fox terrier

Iron also accumulates in the livers of dogs with hepatic disease. In one study, 54 of 95 dogs (56 of which had histologic evidence of hepatic disease) had excessive hepatic iron,[11] whereas in another study, 32 of 34 dogs with CH had increased hepatic iron.[12] Normal hepatic iron is 400 to 1200 ppm, but some dogs had up to 7680 ppm with a mean of 1354 ppm.[11] The presence of iron was correlated with the presence of hepatic injury, but there was not a linear relationship between the amount of iron and the degree of hepatic pathology. The iron accumulated in Kupffer cells and macrophages but not hepatocytes; therefore it was not hemochromatosis as reported in people. Rather, iron accumulation seems secondary to inflammation, necrosis, or copper accumulation (or a combination of these conditions). Some have hypothesized that such secondary iron accumulation in the hepatic parenchyma may aggravate existing hepatic damage.[11]

Alpha-1 antitrypsin (α1-AT), also known as alpha-1 protease inhibitor, has been hypothesized to be a cause of canine CH.[1] Accumulation of a genetically defective α1-AT in hepatocytes in people causes hepatocyte death and low circulating concentrations of α1-AT. As hepatocytes accumulate α1-AT, they die and attract mononuclear cells with cytokines that cause production of more α1-AT. In a study of 57 dogs with hepatic disease, 37 had α1-AT in their livers.[13] The authors noted that α1-AT accumulation was more frequently seen in dogs with chronic progressive hepatitis or cirrhosis. However, it was uncertain whether the α1-AT was the cause or effect of hepatic disease.

Clinical signs of dogs with CH vary with the stage at which they are diagnosed. Because CH is a slow, insidious disease, clinical signs are seldom apparent until the disease is relatively advanced. A patient with a sudden onset of clinical signs may have advanced disease. Dogs presenting in severe hepatic failure (e.g., with cirrhosis) typically are lethargic, depressed, anorexic, vomiting, weak, and have weight loss, polyuria/polydipsia (PU/PD), and/or ascites (or a combination of these problems).[1,2] Diarrhea is relatively common, but is typically not as prominent as is seen in patients with intestinal disease. Icterus is relatively uncommon, and seizures (e.g., hepatic encephalopathy), bleeding, and fever tend to be relatively rare. Dogs that have somewhat advanced disease but are not in severe failure often show lethargy, poor appetite, weight loss, and vomiting as prominent findings. Some animals are fortuitously diagnosed when routine health screening or blood testing for other diseases reveals

occult hepatic disease. These patients may be clinically normal and yet have reasonably advanced disease (even hepatic fibrosis) for which the patient is still compensating. This has major ramifications when considering anesthetic procedures. Hepatocutaneous syndrome is not typically associated with CH, although West Highland white terriers and Cocker spaniels seem to be at increased risk for both.[14]

Clinical laboratory findings in dogs with CH are primarily characterized by increased alanine aminotransferase (ALT),[1–3,12] and approximately 90% have ALTs five to 18 times the upper limit of normal.[2] Serum alkaline phosphatase (SAP) is often increased, but the pattern is often not that of the common steroid hepatopathies in which the SAP is typically many times higher than the ALT. However, if CH progresses to cirrhosis, hepatic enzymes may decrease to the reference range. Hypoalbuminemia, hypocholesterolemia, or both are often present when hepatic insufficiency occurs, and finding these two changes simultaneously strongly suggests either hepatic insufficiency (e.g., cirrhosis) or protein-losing enteropathy. Hyperglobulinemia occurs less commonly (25%) than hypoalbuminemia (40%).[2] Decreased blood urea nitrogen (BUN) may be due to hepatic insufficiency, decreased protein intake, or excessive loss due to polyuria; all of which may occur in patients with CH. Serum bile acids and ammonia tolerance testing are usually abnormal in dogs with CH.

1443

1444

Hypoalbuminemia was reported to be prognostic in one study[2] but not in another.[15] Approximately 75% of cirrhotic patients are hypoalbuminemic[2]; however, not all dogs with hypoalbuminemia have progressed to cirrhosis. Hypoalbuminemia coupled with normal or increased alpha-1 antitrypsin and haptoglobin has been reported in patients with severe hepatic disease that have the potential to recover.[16] Hypoglycemia is rare and has been suggested to have ominous prognostic implications.[2]

Expected hematologic abnormalities include minor anemia (e.g., anemia of chronic disease), sometimes with microcytosis, leukocytosis, and thrombocytopenia (if consumption of platelets occurs). Approximately 10% to 60% of cases have prolonged prothrombin time (PT) and partial thromboplastin time (PTT),[2,3] and a prolonged PT may be prognostic.[2] If ascites is present, it is usually either a modified transudate or a low-protein transudate associated with fibrosis or cirrhosis.

Physical examination is often relatively unremarkable unless ascites is present. Icterus is uncommon, but poor body condition is reasonably typical. Abdominal radiographs are usually unrevealing unless ascites or microhepatia is present. Ultrasonographic changes are typically nonspecific unless obvious microhepatia, ascites, or nodularity of the liver is found. Sometimes multiple acquired portosystemic shunting is detected. Rarely, ultrasound will reveal target lesions.

Definitive diagnosis of CH requires histology. Tru-Cut® needle biopsies can be diagnostic, but they can also miss important histologic changes that surgical or laparoscopic samples are more likely to find. Laparoscopy and surgery allow biopsy of multiple hepatic lobes and can detect gross changes not revealed with ultrasound, thus allowing one to direct biopsy to specific areas of the liver.

Diagnosing CH requires finding inflammation and piecemeal necrosis (i.e., necrosis of the hepatocytes adjacent to the portal tract—the “limiting plate”).[1,3] The inflammation consists primarily of lymphocytes and plasma cells. Small numbers of neutrophils and macrophages may be present; however, granulomatous reactions are not expected in CH. Necrosis first involves destruction of hepatocytes adjacent to the limiting plate, but with time the necrosis extends from the portal area to the central veins (i.e., bridging necrosis). Copper is often present and can be detected by special stains (e.g., rubeanic acid and rhodanine) when it exceeds 400 ppm or by quantitative analysis.[1] Atomic absorption analysis requires approximately 1 g of tissue. The tissue sample should be shipped

frozen or refrigerated to the lab in a copper-free serum blood tube. Formalin may contain copper and can confuse the analysis.[8] Increased Kupffer cell iron stores have been reported in some affected dogs.

Hydropic change (i.e., vacuolar change typical of steroid hepatopathy) is common and may reflect excessive endogenous steroid release due to disease. Nodular regeneration is also commonly seen.[2] Fibrosis is expected in dogs with advanced CH, and cirrhotic change (i.e., regenerative nodules plus severe bridging fibrosis) may be seen. Rarely, portal vein thrombosis occurs, although this is more commonly seen in other inflammatory disorders.

Therapy for CH involves reducing inflammation, alleviating the cause when possible (e.g., reducing hepatic copper levels when they pose a risk to the patient), antioxidant therapy, reducing or preventing fibrosis, treating hepatic encephalopathy, and supportive therapy. (See elsewhere in this text for a detailed discussion of therapeutic principals.)

Reducing inflammation typically involves glucocorticoid therapy.[1,2] Steroids are thought to benefit the patient by their anti-inflammatory effects and by their ability to inhibit fibrosis and stimulate appetite. Glucocorticoids purportedly also decrease intestinal copper absorption. Glucocorticoids typically make the patient feel better and seem to prolong life in patients diagnosed before end-stage hepatic disease occurs.[5] However, if the patient shows signs of advanced hepatic failure, steroids seldom help much. Dexamethasone tends to cause more side effects (e.g., hemorrhagic gastroenteritis) than prednisolone. Iatrogenic hyperadrenocorticism should be avoided. Prednisolone (2.2 mg/kg orally, once a day) is administered, and the dose is tapered as soon as clinical signs and hepatic enzymes evidence substantial improvement. Repeated pulses of high-dose therapy may be needed. Steroids typically cause a further rise in the SAP, although the ALT should decrease if the CH is being controlled. If steroid therapy is ineffective or if excessive side effects occur, azathioprine (Imuran) given at 2.2 mg/kg orally, every other day may be beneficial. Concurrent use of allopurinol increases the likelihood of toxicity from azathioprine.[2]

Oxidation is a significant mechanism of hepatic damage, as seen when excessive copper is accumulated[2]; therefore antioxidants are typically administered. Although no critical studies are available that demonstrate efficacy in dogs with CH, water-soluble Vitamin E is typically administered (400 to 600 IU orally, once a day) because of its safety, minimal cost, and potential benefit. S-adenosyl-L-methionine (SAMe), a precursor of glutathione and a methyl donor for methylation reactions, has benefited animals and people exposed to excessive alcohol.[17] Milk thistle, a herbal compound used for hepatic disease in people, has silymarin as the active complex. Silymarin increases superoxide dismutase in cells and serum concentrations of glutathione and glutathione peroxidase.[18] A meta-analysis showed that milk thistle was safe and well tolerated in people with chronic hepatic disease. It did not have a demonstrable effect on outcome in most cases, but one study showed that people with alcoholic cirrhosis were benefited.[18]

Ursodeoxycholic acid has a hepatoprotective effect, probably due to displacing hydrophobic bile acids (e.g., lithocholic acid) from hepatocyte membranes, and has also been touted as having immunomodulatory properties.[2] Its use at 15 mg/kg orally, once a day in a dog with CH was associated with improvement of hepatic enzymes.[1] It rarely causes diarrhea, but does have a hypercholeretic effect and should not be administered to dogs with biliary tract obstruction.

Patients with excessive hepatic copper accumulation (2000 ppm) should be treated with copper chelation therapy, oral zinc therapy, or both to prevent absorption of copper. Copper chelation typically involves administering penicillamine (10 to 15 mg/kg orally, twice a day). Affected Belingtons treated with penicillamine can lose 900

ppm copper per year,[8] whereas other breeds (e.g., Doberman pinschers) may respond faster.[1] Some patients experience clinical improvement despite persistence of hepatic copper concentrations. Penicillamine seems to have anti-inflammatory effects and inhibits fibrosis. Penicillamine therapy causes vomiting in approximately 30% of treated animals, and administering it with food may decrease such side effects. Trientine (10 to 15 mg/kg orally, twice a day) may be substituted if penicillamine cannot be tolerated. Trientine causes fewer side effects, may affect a different body pool of copper than penicillamine, and is effective in patients with hemolytic anemia due to copper release from necrotic hepatocytes.[8] One dog developed clinical copper deficiency (i.e., microcytic anemia and hepatic dysfunction) due to trientine chelation therapy coupled with a controlled copper diet.[19] 2,3′, 2-tetramine is more effective at chelating copper than trientine, but it is not commercially available.[8]

1444 1445

Chelation therapy can be combined with oral administration of zinc to decrease intestinal copper absorption. It has been suggested that zinc therapy only prevents further accumulation of copper; however, in one study of three Bedlingtons and three West Highland white terriers administration of zinc significantly decreased hepatic copper concentrations after 2 years of therapy.[8] Administering zinc salts (e.g., zinc acetate or zinc gluconate initially given at 5 to 10 mg elemental zinc/kg twice a day) 1 hour before meals induces metallothionein (a copper-binding protein) in enterocytes. Dietary copper binds to this protein, is not absorbed, and is eventually evacuated from the body when the enterocyte is sloughed. Excessive zinc can cause hemolytic anemia, and blood zinc concentrations need to be checked periodically. Diets lower in copper can augment other therapy, but such diets are inadequate by themselves if the patient is already symptomatic for excessive hepatic copper concentrations.[8]

H-2 receptor antagonists, Carafate, or both are sometimes administered because hepatic disease has been suggested to cause gastroduodenal ulceration.

227.2 FIBROSIS AND CIRRHOSIS

Fibrosis and cirrhosis may result from any severe or chronic hepatic insult. Inflammatory cells cause hepatocellular necrosis, which creates space (i.e., hepatocyte dropout) that is filled by more inflammatory cells. The liver's response to necrosis is to produce hepatocytes and bile duct epithelium. However, lysosomal proteases and radicals released by inflammatory cells disrupt normal hepatic extracellular matrix (ECM) and cellular membranes causing release of substances (e.g., transforming growth factor-beta [TGF-β]) that attract collagen-producing cells. Fibrosis causes ECM modification, and hepatocytes growing on it may have functional alterations.[2,20]

Dogs with acute massive necrosis or CH often develop hepatic fibrosis. Because fibrosis follows the course of inflammation and necrosis, a disease that produces inflammation in the portal areas that reaches out to lobules and other portal areas causes bridging fibrosis (i.e., there is a “bridge” of fibrous connective tissue from one portal area to another). In some cases, fibrosis extends from the portal triad to the hepatic veins. When bridging fibrosis causes permanent distortion of the liver associated with regenerative nodules, it is termed *cirrhosis*. Fibrosis that cuts across acinar zones causes micronodular cirrhosis. Fibrosis that divides the liver into groups of acini with more than one portal tract within each nodule causes macronodular cirrhosis. Fibrosis that only surrounds bile ducts causes biliary cirrhosis. If fibrosis is severe, collagen limits the ability of vessels and sinusoids to distend, thereby increasing resistance to blood flow. Collagen around hepatocytes impairs sinusoidal blood flow and the sinusoidal endothelium's selective permeability, decreasing hepatocyte function. As cirrhosis persists, the type of collagen laid down may be less susceptible to collagenase activity, making it harder to remove.[2] Cirrhotic patients are at increased risk for anesthetic-related complications.

Preventing fibrosis is an important long-term goal in patients with any chronic inflammatory disease. Prednisolone, azathioprine, penicillamine, zinc, and vitamin E appear to have antifibrotic effects.[1,20] Once severe fibrosis has occurred, colchicine therapy may be considered. Colchicine is a microtubule assembly inhibitor that increases collagenase activity. Colchicine (0.03 mg/kg orally, once a day) was associated with improved histology (i.e., decreased fibrosis) in one dog. It has been used in other dogs, but it is difficult to confidently ascribe beneficial results to colchicine because of limited experience.[2] Although frequently prescribed, no controlled drug trials have proven its value.

227.2.1 Chronic Hepatitis in the Doberman Pinscher

Middle-aged, female Doberman pinschers are at increased risk for severe CH with subsequent cirrhosis.[1,2,21] Clinical presentation and clinical pathology findings are as described under CH, but PU/PD, splenomegaly, neutrophilic leukocytosis, normal to increased PCV,[2] and bleeding may be more common than in affected patients of other breeds. Because these dogs are particularly prone to severe CH and cirrhosis, they are noticeably fragile; even minimal anesthesia can cause severe, acute decompensation. Many patients with clinical illness die within weeks of first signs of disease. Some affected Dobermans are referred for suspected diabetes insipidus due to severe PU/PD. If CH is diagnosed fortuitously in an asymptomatic dog, the life expectancy after diagnosis is presumably longer; however, early therapy in asymp-tomatic patients has not been proven to substantially increase life span.

Approximately 8% of Dobermans in Finland had an increased ALT; however, not all Dobermans with an increased ALT had CH.[1] Some Dobermans with increased ALT values lived for months and in some cases years without clinical signs of CH.[22] In a more recent study, 18 Dobermans with subclinical CH were biopsied, and all had excessive hepatic copper concentrations. Initially there was parenchymal and portal inflammation, but the parenchymal inflammation diminished and the portal inflammation increased as the disease progressed. There was expansion of portal areas with necrosis, fibrosis, and bile duct proliferation.[21] Five dogs lived for 3 years; as a group they were asymptomatic for an average of 19 months.

Even though female Doberman pinschers are clearly at risk for severe CH, not all Doberman pinschers with hepatic disease have CH. Doberman pinschers also appear to be at risk for drug-induced hepatic disease (e.g., diethylcarbamazine, oxibendazole, amiodarone). Therefore hepatic biopsy is recommended for Dobermans with an increased ALT if the patient is not an undue anesthetic and biopsy risk. Periportal copper accumulation, hepatonecrosis, and inflammation are expected in early cases,[1,2] although one report suggested that the earliest inflammatory and fibrotic lesions are around hepatic veins.[23] Eventually a substantial hepatic necrosis occurs, with neutrophilic and macrophage infiltrates. Excessive hepatic copper levels are common, and Doberman pinschers as a breed have been suggested to have higher hepatic copper levels than some other breeds. However, five of 35 Dobermans with CH had normal hepatic copper levels,[23] and even Dobermans with substantial copper accumulation generally do not attain the concentrations often seen in severely affected Bedlington terriers.[2] Therefore although it is not clear if the copper accumulation is innocuous or pathogenic, it is not an initiating cause of CH as in Bedlington terriers. Hepatic iron concentrations tend to be increased. Because of their increased risk for CH, it is reasonable to routinely screen Doberman pinschers for biochemical evidence of hepatic disease. Therapy depends upon the stage of the disease, but usually consists of antioxidants and glucocorticoids ± azathioprine. Copper chelation and antifibrotic therapy are used as indicated by histopathology.

227.2.2 Chronic Hepatitis Associated with Copper Accumulation in the Bedlington Terrier

Bedlington terriers in the United States have historically had a high incidence of an autosomal-recessive metabolic defect in biliary copper excretion (approximately 60% of tested dogs).[8] The gene responsible for this defect is different from that causing Wilson's disease in people. Bedlingtons homozygous for the trait progressively accumulate copper in their livers, which typically causes oxidative mitochondrial damage after reaching approximately 2000 ppm. Bedlingtons may begin accumulating copper *in utero*.[24] Their hepatic copper content continually increases throughout their lives (see following) and may reach 12,000 ppm.[2] Once sufficient copper has accumulated in the liver, otherwise insignificant stress may trigger acute hepatic necrosis, possibly with acute hemolysis and renal failure due to release of large amounts of copper from dying hepatocytes.[1,2]

An increased ALT is usually the first clinicopathologic evidence of disease; however, this increase does not occur until excessive hepatic copper accumulation is associated with hepatocyte damage and inflammation. Younger dogs with excessive hepatic copper but no inflammation often have normal ALTs.[2] As hepatic damage occurs, increased ALTs may be found in clinically normal animals. Clinical signs may be those of acute hepatic disease (e.g., vomiting, anorexia, lethargy) from which they may recover; chronic hepatic failure (e.g., anorexia, vomiting, depression, loss of body condition) that ultimately progresses to obvious hepatic failure with jaundice, ascites, and hepatic encephalopathy; or acute hepatic failure coupled with hemolytic anemia and jaundice.[2]

Measuring serum or plasma copper or ceruloplasmin concentrations is not helpful; definitive diagnosis requires hepatic histopathology. Accumulation of copper in lysosomal granules is the first histologic abnormality. As hepatic copper levels increase, random areas of focal inflammation occur. Inflammatory infiltrates extend out from the portal triads as the disease progresses, with occasional bridging necrosis and some fibrosis. Finally cirrhosis occurs.[8] Hepatic copper levels increase until about 6 years of age, and then they begin to decrease, probably because copper-laden hepatocytes are replaced with scar tissue or regenerative nodules.[1,2] Hepatic iron concentrations are also increased.

Identifying and removing affected dogs from the breeding pool is the desired approach. Selective breeding in the Netherlands has decreased the prevalence from 46% (1976 to 1986) to 11% (1990 to 1997).[25] When screening asymptomatic animals, one may biopsy at 6 and 15 months of age. Unaffected dogs will have normal amounts of hepatic copper both times, heterozygotes will initially have a high copper concentration that lessens by the second biopsy, and homozygotes will initially have excessive copper that is increased at the second biopsy.[8] The Orthopedic Foundation for Animals (www.offa.org/index.html) has a registry for unaffected Bedlington terriers that uses a DNA marker tightly linked to the expression of copper toxicity.[26] However, a study of 154 hepatic biopsies from Bedlingtons found that the DNA marker did not reliably identify copper intoxication in individual dogs.[27] This discrepancy may have been due to studying different subpopulations of Bedlingtons. Fecal excretion of ^{64}copper discriminates between affected and nonaffected West Highland white terriers and Bedlingtons.[28] However, the test requires special facilities and is not as specific as desired.

Feeding a relatively low copper diet and administering oral zinc is usually beneficial in affected, asymptomatic dogs. Chelator therapy may also be used, and penicillamine therapy has apparently prevented

disease progression in some dogs that continue to have excessive copper. Affected animals may live a normal life if therapy starts when they are young.[8]

227.2.3 West Highland White Terriers

West Highland white terriers have a genetic tendency toward higher hepatic copper concentrations than most other breeds, and CH is more common in West Highland white terriers. However, not all West Highland white terriers with CH have inflammation that is clearly associated with excessive hepatic copper accumulation.[1,2] Furthermore, many West Highland white terriers with modest copper accumulation do not develop CH. In distinction to what occurs in Bedlington terriers, West Highland white terriers that accumulate copper in their livers do not do so for their entire lives, and the values tend to decrease over time.[9] Finally, West Highland white terriers usually do not achieve hepatic copper levels greater than 3500 ppm, in distinction to Bedlington terriers, which often achieve levels greater than or equal to 5000 ppm.

Histopathology of West Highland white terriers livers may show normal liver with excessive copper; multifocal hepatitis with excessive copper, and cirrhosis with excessive copper.[2] Dogs with CH are treated as previously described.

227.2.4 Dalmatians

Dalmatians have recently been recognized to develop necroinflammatory hepatitis associated with increased hepatic copper concentrations.[4] Too few animals have been diagnosed to delineate whether or not an age or sex predilection exists. Affected animals have typical signs of hepatic disease (e.g., anorexia, vomiting, lethargy). Increased ALT was the predominant clinicopathologic finding, whereas lesser increases in SAP were common. Hypoalbuminemia and hyperbilirubinemia were seen in some dogs. Ultrasound findings were typically normal. Piecemeal necrosis and bridging fibrosis were the most common histologic findings, and inflammatory infiltrates were either lymphocytic or neutrophilic. Hepatic copper concentrations ranged from 754 to 8390 ppm, with an average of 3197 ppm. Average life span after diagnosis was 80 days, with some animals living to 240 days postdiagnosis.

227.2.5 Skye Terriers

At least some bloodlines of Skye terriers seem to have a tendency to have CH. Although not well characterized, it appears that the CH occurs first and that hepatic copper accumulation is an inconsistent secondary effect of the inflammatory lesion. Hepatic copper concentrations up to 2257 ppm have been reported. The first histologic lesion is intracanalicular cholestasis.[1,2]

227.2.6 Cocker Spaniels

Young male cocker spaniels are at increased risk for early onset CH that quickly becomes cirrhotic. The mean age at presentation of 16 affected dogs was 5.6 years, and males were preferentially affected.[29] Most had ascites (11 of 16) of less than 2 weeks' duration. A mature neutrophilic leukocytosis and ascites (either a transudate or a modified transudate) were typical. ALT was usually increased, but hyperbilirubinemia was a mild, inconsistent finding. Biopsy typically reveals a periportal hepatitis consisting primarily of plasma cells and lymphocytes with limiting plate destruction. Severe bile duct duplication was common. Copper accumulation was inconsistent. One study looking at α1-AT and its relationship to CH in cocker spaniels

concluded that the two were not related.[13] Because the disease is typically advanced at the time of diagnosis, prognosis is grim. Most clinically affected dogs die within a month of diagnosis, although occasional patients may live for up to a year with supportive therapy.[2]

227.2.7 Infectious Canine Hepatitis and its Possible Association with Chronic Hepatitis

Canine adenovirus was found in the liver of five out of 53 dogs with CH; however, another study failed to find it in any of 45 dogs with hepatic disease.[1,2] Whether a cause-and-effect relationship exists is unknown. Some people have hypothesized that the viral infection initiates a self-perpetuating inflammatory hepatic disease. Experimental exposure of partially immunized dogs has produced CH.[2]

1446 1447

227.3 CHOLANGIOHEPATITIS

Cholangiohepatitis is diagnosed by finding mixed inflammatory infiltrates in the periportal (i.e., zone I) area, usually with inflammation extending through and into the bile ducts.[12,15] Icterus is common, and ALTs, SAPs, and serum bile acids tend to be higher than is seen with CH. However, one cannot discriminate between dogs with CH and those with cholangiohepatitis based upon laboratory values. In one study, median survival time (MST) was 25 months.[2,15]

227.4 DRUG-ASSOCIATED HEPATITIS

Although almost any drug will eventually be associated with hepatotoxiciy in some individual, some drugs are frequently associated with hepatic damage. Most hepatotoxic drugs cause hepatocellular degeneration, necrosis, or fibrosis with minimal inflammation. Inflammatory infiltrates have been associated with trimethoprim-sulfadiazine, phenobarbital, diethylcarbamazine and oxibendazole, and amiodarone, although they are usually relatively mild and do not closely resemble CH. However, the degree of inflammation associated with apparent drug toxicity is variable, and some animals have substantial inflammation. Whether the inflammation is due to the drug or some other, concurrent problem is unknown.[1,30,31]

227.5 ACIDOPHIL CELL HEPATITIS

This is a transmissible disease (apparently viral) that has been reported affecting dogs in the United Kingdom. In the acute phases, it is associated with relatively little hepatic inflammation. However, it is believed that CH and cirrhosis may result. Increased hepatic enzymes are expected, and diagnosis requires hepatic biopsy. The characteristic lesion is finding acidophil cells throughout the parenchyma with an angular shape and acidophilic cytoplasm.[1,2]

227.6 LEPTOSPIROSIS

The most common clinical presentation of dogs with leptospirosis is acute renal failure. Depending upon the serovar involved, dogs may or may not have concurrent hepatic disease (i.e., increased SAP and hyperbilirubinemia). In one recent study, 20 of 36 dogs with leptospirosis had hepatic involvement[32]; however, the lesion characteristic of acutely affected dogs is edema and sinusoidal congestion, with perhaps a mild neutrophilic and eosinophilic infiltrate. Serovar grippotyphosa has been suggested to be able to cause CH. In one kennel, five American foxhounds were diagnosed with CH. Four had leptospires in their canaliculi. In another

report, beagles vaccinated against leptospirosis developed CH, and leptospires were found in their bile canaliculi.[1,2]

227.7 LOBULAR DISSECTING HEPATITIS

This is characterized by finding inflammatory cells diffusely throughout the hepatic lobule as opposed to primarily in the periportal regions, and collagen and reticulin fibers dissecting around small groups of hepatocytes and sometimes single hepatocytes.[1,2] Copper may be found in the liver, but it appears to be a secondary event. This syndrome appears most commonly in neonatal and juvenile dogs (e.g., mean of 11 months old in one series). Hepatic enzymes are typically increased, and ascites associated with portal hypertension is probably the most common presenting clinical sign. Standard poodles may be at increased risk for hepatitis, but it is not certain that it is lobular dissecting hepatitis. One paper reported three standard poodles with a disease that resembled lobular dissecting hepatitis but which did not cause ascites.[33] Regardless of whether or not these dogs had lobular dissecting hepatitis, a breed predisposition seemed likely.

227.8 GRANULOMATOUS HEPATITIS

Granulomatous hepatitis is an uncommon hepatopathy differing from CH in that macrophages are a predominate finding. The lesion tends to be multifocal and can be caused by numerous bacteria (e.g., *Nocardia*, *Mycobacterium*, *Rhodococcus*, *Borrelia*, *Bartonella*), fungi (e.g., histoplasmosis, coccidioidomycosis), and parasites (e.g., *Hepatozoonosis*, *Heterobilharzia*). In people, occult lymphoma has been implicated. However, many cases of canine granulomatous hepatitis are idiopathic.[2] One report of nine dogs with granulomatous hepatitis found intestinal lymphangiectasia in two, lymphosarcoma in one, and histiocytosis in one.[34] In three cases, the cause was uncertain. Clinical signs vary widely, and no breed or age predisposition is recognized for idiopathic disease. Special stains for bacteria and fungi are warranted, as is serology for selected agents. Culture for bacteria including atypical mycobacteria (which can be hard to find, even with special stains) is desirable. If one cannot find a cause, it is usually prudent to first treat for a possible undiscovered agent (e.g., atypical mycobacteria, *Bartonella* spp.) and only resort to immunosuppressive therapy after diagnostic efforts and therapeutic trials have failed.

228 CHAPTER • 228 Feline Inflammatory Liver Disease

Sarah M.A. Caney

Timothy J. Gruffydd-Jones

The most important and common hepatic disorders of cats in which inflammation is the predominant pathologic change are the different forms of the cholangitis and cholangiohepatitis complex. Inflammatory lesions are a feature of some other feline disorders that affect the liver, but other pathologic features dominate. These include infectious diseases such as feline infectious peritonitis (FIP), protozoal infections (most notably toxoplasmosis), bartonellosis, and hepatotoxicities particularly associated with drugs including diazepam and tetracyclines.

228.1 CHOLANGITIS AND CHOLANGIOHEPATITIS COMPLEX

The cholangitis and cholangiohepatitis complex is regarded as the second most common hepatic disorder in cats in the USA after idiopathic hepatic lipidosis.[1] In countries in which hepatic lipidosis is less common, such as the United Kingdom, the cholangitis and cholangiohepatitis complex may constitute the most common primary hepatic disorder of cats.

Considerable confusion exists over the classification and terminology used to describe different forms of the cholangitis and cholangiohepatitis complex, and this is the most contentious issue relating to feline inflammatory liver disease.

228.1.1 Pathology and Classification

Different variants of the complex have been described based on histopathologic features of the lesions including the predominant nature of the inflammatory cellular infiltrate (i.e., neutrophilic, lymphocytic) and bile duct proliferation and presence of fibrosis.[2]

It is currently difficult to devise a classification of feline inflammatory liver diseases incorporating cholangitis and cholangiohepatitis that will reconcile all the previously reported cases and forms of the classification used. The most striking feature of the lesions is generally whether they are suppurative with a prominent neutrophilic infiltration or whether the inflammatory infiltrate is predominantly lymphocytic in nature. This is the basis for the classification of cholangitis and cholangiohepatitis. It correlates with distinctly different clinical presentations and has practical relevance to the management of affected cats.

228.1.2 Suppurative Cholangitis and Cholangiohepatitis

The dominant feature in suppurative cholangitis and cholangiohepatitis is evidence of a suppurative process within the bile ducts. The infiltrate is primarily of neutrophils, although there may be a range of inflammatory cells including lymphocytes and plasma cells. Disruption of the limiting plate occurs with infiltrate extending into the portal areas.[2] Periportal necrosis is common. The bile ducts themselves show necrosis and degeneration with pyknosis, variation in nuclear appearance, and cytoplasmic vacuolation. The extent of fibrosis is variable and probably reflects the duration or stage of the disease process (Figure 228-1B).

Other specific disease entities frequently accompany suppurative cholangitis. The most commonly reported of these is pancreatitis, characterized histologically by periductal infiltration, acinar degeneration, fibrosis, and nodular hyperplasia. The extent of the pancreatitis is generally mild. Coexisting pancreatitis has been described in the majority of reported cases of cholangiohepatitis and was identified in 50% of 18 cases of cholangiohepatitis in a retrospective pathologic study.[3]

Inflammatory bowel disease (IBD) has been recognized more recently as a coexisting feature in cholangiohepatitis. It was diagnosed in 83% of cats with cholangiohepatitis in a retrospective pathologic study.[3] Although the intestinal inflammatory infiltrate was predominantly lymphocytic and plasmacytic in nature, in some cases a neutrophilic element was present.

The term *triaditis* has been used to describe a syndrome of concurrent cholangiohepatitis, pancreatitis, and IBD. The association of these entities may indicate a common underlying disease process in some cases. Suppurative cholangitis is believed to result from ascending infection of the biliary tract. Bacteria can generally be cultured from the bile of affected cats, and a mixed growth of bacteria is often recovered (comprised of common inhabitants of the intestinal gut flora). Ascending infection from the intestine is also believed to be an important factor in the development of pancreatitis.[4] The pancreatic and bile ducts are joined before entering the duodenum and this may predispose to concurrent development of pancreatitis and suppurative cholangitis. It is possible that the presence of IBD may predispose to ascending infection. In triaditis the predominant clinical features are most often associated with the cholangitis, with the pancreatitis and IBD being identified as complications.

228.1.3 Lymphocytic Cholangitis

In some cases of feline inflammatory liver disease the inflammatory infiltrate is predominantly lymphocytic.[5,6] (Figure 228-2B) In a proportion of these cases the inflammatory infiltrate consists purely of lymphocytes and is restricted to the portal areas. It has been suggested that this is a specific form of feline inflammatory liver disease that has been termed *lymphocytic portal hepatitis*.[7] It is reported to occur in older cats.[7] Assessment of the significance of this pathologic change is complicated by the recognition that lymphocytic portal infiltrates are common in older cats not showing any clinical evidence of liver disease. Over 90% (29 of 30) of cats more than 15 years of age were described as having portal lymphocyte infiltrates in one survey.[8]

In other cases, although lymphocytes predominate, the inflammatory infiltrate is mixed with variable numbers of other inflammatory cells, particularly neutrophils. The infiltrate may be more extensive, appearing as marked aggregates of lymphocytes in the form of lymphoid follicles sometimes surrounding bile ducts or as a more diffuse infiltrate within portal areas. Changes are evident in the biliary tree, with bile duct proliferation and sometimes inflammatory changes within the walls of the bile ducts. However, usually no epithelial degeneration or inflammatory infiltrate exists within the lumen of the bile ducts. Fibrosis is present to a variable extent, and this may be severe in chronic cases. This initially has a distinctive septal or monolobular pattern, with bridging fibrosis between the portal areas. The fibrosis is not associated with venules and does not lead to pseudolobule formation but frequently results in prominent nodular hyperplasia. There may be disruption of the vasculature with increased prominence of small blood vessels on the surface of the liver.

Table • 228-1 Comparison of Suppurative and Lymphocytic Cholangitis

	LYMPHOCYTIC CHOLANGITIS	SUPPURATIVE CHOLANGITIS
Predispositions	Younger cats Persians	Middle aged/older cats
Clinical Features	Often bright	Usually depressed, ill
Appetite	May show polyphagia	Usually anorexic
Jaundice	±	+
Ascites	±	–
Lymphadenopathy	±	–
Hepatomegaly	±	–
Laboratory Changes		
Neutrophilia	±	+
Lymphopenia	±	–
↑ALT	+	+
↑ALP	+	+
±Bilirubin +	+	+
+Bile acids	±	+
↑Globulins	+	–
Ultrasound	±Hyperechoic liver	±Hyperechoic liver biliary stasis
Pathology		
Cellular infiltrate	Primarily lymphocytes	Primarily neutrophils
Distribution of lesions	Mainly portal	Mainly bile ducts
Fibrosis	Variable/can be extensive	–
Association with other disorder	? Pancreatitis	Pancreatitis/IBD
Treatment	Immunosuppressive corticosteroids	Antibiotics Choleretics

Parallels have been drawn between lymphocytic cholangitis and some forms of inflammatory liver disease in man that are characterized by lymphocytic infiltration such as sclerosing cholangitis, biliary cirrhosis, and pericholangitis; however, important differences in the histopathologic features exist. In occasional cats the fibrosis may be prominent around the bile ducts as a concentric distribution, and this has been termed *sclerosing cholangitis*.[9] However, differences exist compared with sclerosing cholangitis in man, and it may simply represent a variant form in the distribution of fibrosis of lymphocytic cholangitis.

It is not clear whether what has been termed as *lymphocytic portal hepatitis* is a distinct separate entity or a variant of lymphocytic cholangitis. The similarities in terms of the lymphocytic predominance, biliary involvement, and pattern of fibrosis, are more striking than the differences; therefore the latter appears more likely. IBD and pancreatitis have been reported to be common in cases described as lymphocytic portal hepatitis.[3] Pancreatitis has been recognized in combination with lymphocytic cholangitis but previous reports do not reveal any evidence of a striking association.[5]

There has been some preliminary characterization of the immune-cell infiltration in lymphocytic cholangitis.[10] The infiltrative lymphocytes are predominantly CD3-positive T cells with smaller numbers of associated B cells. Occasional IgA-positive plasma cells are present, and increased MHC II expression by a variety of immune cells occurs. The nature of this infiltrate suggests, not unexpectedly, that an immune-mediated mechanism may play a role in the pathogenesis of the liver pathology. In the liver diseases of man that bear some similarity, sclerosing cholangitis and biliary cirrhosis, autoantibodies against liver cell components are identified. However in the limited studies that have been reported, no evidence of such antibodies have been found in affected cats.[5]

There may be some initiating factor that triggers the development of lymphocytic cholangitis leading to immune-mediated mechanisms that perpetuate liver pathology. Clinical signs may not arise until this stage has been reached.

1449

1450

It has been postulated that lymphocytic cholangitis and suppurative cholangitis may be essentially part of the same disease syndrome, with lymphocytic cholangitis representing a chronic stage of an earlier suppurative process.[1] A mixed inflammatory cell infiltrate in some cats is identified that probably represents progression of suppurative cholangitis to a more chronic form (see following), but the authors believe that this is distinct from lymphocytic cholangitis. Key features suggest lymphocytic cholangitis is a separate, distinct disease syndrome:

- No evidence suggests that cats diagnosed with lymphocytic cholangitis have had earlier episodes of liver disease or that cats with suppurative cholangitis are at greater risk of developing lymphocytic cholangitis.
- Lymphocytic cholangitis occurs most frequently in younger cats, but suppurative cholangitis tends to occur in middle-aged to older cats.
- An inflammatory infiltrate is found in the bile ducts of cats with suppurative cholangitis but not in lymphocytic cholangitis.
- Concurrent pancreatitis is common in cats with suppurative cholangitis but is unusual in lymphocytic cholangitis.

These two latter findings implicate ascending infection in the pathogenesis of suppurative cholangitis, but no evidence suggests it plays a role in the development of lymphocytic cholangitis.

228.1.4 Mixed Inflammatory Infiltrates

A small proportion of cats with inflammatory liver disease show a mixed cell infiltrate consisting of both neutrophils and lymphocytes. They show bile duct proliferation with epithelial degeneration and necrosis but also have inflammatory infiltrates within the lumen of the bile ducts that differentiate them from the cases of lymphocytic cholangitis with a mixed cell infiltration. It is plausible that these cases represent a chronic stage of earlier episodes of suppurative cholangitis.

228.2 SUPPURATIVE CHOLANGITIS AND CHOLANGIOHEPATITIS

228.2.1 Clinical Features

Suppurative cholangitis occurs more frequently in middle-aged and older cats. In one series of reported cases, all affected cats were over 10 years of age.[7] No apparent sex or breed predisposition exists. Most cats in which a diagnosis of suppurative cholangitis is made are presented as sick cats with acute illness.[1] They are usually anorexic and may be pyrexic. Jaundice is the most consistent specific clinical sign and is caused by intrahepatic cholestasis, sometimes with extrahepatic biliary obstruction. There may be evidence of abdominal pain and resentment on abdominal palpation. Some cats with suppurative cholangitis may have milder or more chronic disease that may be overlooked.

228.2.2 Diagnosis

The most consistent changes on routine laboratory evaluation are increases in ALT and bilirubin. Cholestatic enzymes, ALP, and γGT are usually increased, and usually raised fasting or postprandial (or both) serum bile acid concentrations are found. It is reported that some cats with cholangitis have normal liver enzymes, although in the authors' experience this is rare. The most common finding on hematology is a leukocytosis with neutrophilia and left shift. There may be suppression of hepatic production of clotting factors in the form of prolonged clotting times and increased PIVKA levels,[11] although spontaneous clinical complications of impaired hemostatic function are rare.

The principal abnormalities on imaging are related to the extrahepatic biliary tract. Evidence of gallbladder distension usually exists, and the bile duct may appear prominent.

Cholelithiasis is occasionally seen in cases of suppurative cholangitis, and the majority of reported cases of cholelithiasis have been associated with suppurative cholangitis. It is not clear whether cholelithiasis is the primary problem leading to suppurative cholangitis as a complication, or, as seems more plausible, suppurative cholangitis predisposes to cholelithiasis. Gallstones can be radiolucent, although calcification is a common feature (Figure 228-1A). On ultrasonography, choleliths cause acoustic shadowing. This can aid diagnosis of translucent stones, although inspissated bile, inflammatory, and neoplastic masses may have a similar appearance. Other ultrasonographic features that may be seen with suppurative disease include thickening of the gallbladder (wall thickness >1 mm), distension of the bile duct (>5 mm), and the presence of sludging or inspissation of bile.[12] There may be general patchy echogenicity of the liver.[13]

Histopathology is necessary for confirmation of diagnosis of suppurative cholangitis. A number of techniques can be used to obtain suitable biopsies for histopathologic examination. Fine needle aspirates offer the most noninvasive method of collecting samples. These may confirm the presence of a suppurative process but do not allow assessment of liver architecture and can be misleading.[14,15] Fine needle aspirates can be submitted for bacteriologic isolation and should be maintained in an anaerobic environment until culture is performed. Wedge biopsy at exploratory laparotomy enables direct visualization of the liver and biliary tree and provides the ideal specimen for pathologic assessment. The patency of the bile duct can be established by applying gentle pressure to the gallbladder. Bile should be aspirated for gross assessment and to provide a sample for culture. Immediate cytologic evaluation of a smear of bile will confirm neutrophilic infiltration in suppurative cases. The bile frequently becomes extremely inspissated in suppurative cholangitis, and aspiration may necessitate use of a wide bore needle. Exploratory laparotomy provides the opportunity to examine the pancreas for evidence of pancreatitis and to obtain biopsies where appropriate. It also enables collection of full-thickness intestinal biopsies to investigate the possibility of concurrent IBD. Biopsies suitable for assessment of hepatic architecture can be obtained percutaneously using a suitable liver biopsy needle such as a Tru-Cut° biopsy needle. Ultrasound guidance allows more accurate placement of the biopsy needle. If the required equipment and expertise is available, laparoscopy offers the best compromise between minimizing invasiveness while allowing visualization and biopsy. Hepatic biopsies should be submitted for bacteriologic culture in addition to histopathology.

228.2.3 Treatment

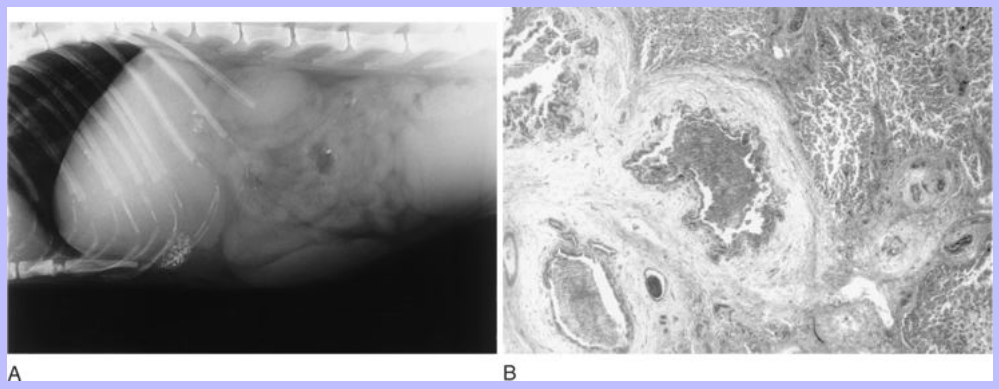
Antibiotic treatment is the priority for suppurative cholangitis. The choice of antibiotic should ideally be based on the results of culture of bile and sensitivity tests. However initial selection of antibiotic must be made before results of bacteriologic culture are available. *E. coli* is the most frequently isolated organism but a

mixed growth (including anaerobes such as *Bacteroides* spp. and other organisms that constitute the normal small intestinal bacterial flora), is frequently found, reflecting ascending infection from the gut. The ideal feature of an antibiotic selected for empiric use is that it should be broad spectrum, bactericidal, achieve therapeutic levels in bile, and not require hepatic metabolism for activation or excretion. The authors' initial choice is therefore generally a potentiated synthetic penicillin (e.g., amoxicillin-clavulanate), cephalosporin (e.g., cephalexin), or fluoroquinolone combined with metronidazole for additional activity against anaerobes. Chloramphenicol has sometimes been recommended[1]; however, high levels can accumulate in the presence of biliary stasis, and toxic effects may result. Antibiotic treatment is maintained for at least 4 to 6 weeks to minimize the risk of recurrence.

1450

1451

Figure 228-1 **A** and **B,** Lateral radiograph of a cat with suppurative cholangitis showing a calcified choleliths. Hepatic histology from the same case.



The benefits of corticosteroid therapy are widely accepted for lymphocytic cholangitis (see following) and probably also for chronic nonsuppurative cholangitis associated with mixed inflammatory infiltrates. The use of corticosteroids for acute suppurative cholangitis may have benefits in some cases when used judiciously at anti-inflammatory doses for short periods (e.g., prednisolone at 1 mg/kg daily) based on facilitating bile flow through reducing biliary tract inflammation.

Cholecystectomy may be necessary in some cases to remove inspissated bile. This should be followed by lavage and flushing to ensure patency. This may require cannulation of the duodenal papilla. If complete obstruction of biliary flow is identified at laparotomy, cholecystoduodenostomy is indicated to re-establish biliary flow. The peri-and postoperative mortality rate for cats requiring surgical intervention is high.[16]

Supportive measures aid in the management of suppurative cholangitis. Fluid therapy is likely to be required initially, and in most cases nutritional support is also needed. In the longer term modified diets formulated for liver support are indicated, but in the early stages maintenance of calorific intake is the priority. Suitable diets should be easily digested with reduced protein and supplemented with arginine and carnitine.

Choleretics are of value in promoting bile flow, and this is indicated if extraheptic biliary obstruction is not present. The beneficial effects of ursodeoxycholic acid include changing the composition of the bile acid pool by reducing the proportion of hydrophobic bile acids that have toxic effects on hepatocellular membranes. A dose of 10 to 15 mg orally, once a day is used. No controlled clinical trials have been reported to demonstrate

a beneficial effect of UDCA, but it is widely used and appears to be safe.[17] Vitamin K supplementation is indicated if defects in clotting function are identified, particularly prior to any biopsy or surgical procedure. A dose of 5 mg of Vitamin K is given orally or subcutaneously. The response to treatment can be assessed by monitoring PIVKA concentrations and clotting function, which are usually restored to normal in a few days.[11]

More recently S-adenosyl-L-methionine (SAMe) has been used as a nutraceutical agent in the support of cats with liver disease. One beneficial effect is believed to be the restoration of glutathione levels that are reduced in liver disease, leading to increased oxidative damage and exacerbation of liver disease. Other beneficial effects may be to increase levels of cysteine and taurine, which are required for bile acid conjugation and a cytoprotective effect. Although theoretic potential benefits to SAMe exist, no trials have been reported that confirm this.

228.2.4 Prognosis

Information on the prognosis for suppurative cholangitis is limited. In one study just over half (8 of 15) of cats survived for more than 1 year after the diagnosis was made with a median survival time (MST) of 29 months.[18] This concurs with the authors' limited experience that suppurative cholangitis has a reasonable prognosis. Some cases do appear to recur shortly after initial treatment and this risk may be reduced by ensuring prolonged antibiotic treatment, preferably selected on the basis of culture and sensitivity testing. Suggestions that suppurative cholangitis may progress to lymphocytic cholangitis is not supported by evidence, and the authors have not observed any cases of such progression. The prognosis for cats that require surgical intervention to restore bile flow is much more guarded.[16] Concurrent presence of pancreatitis and IBD complicates the prognosis for suppurative cholangitis and the choice of treatment. Management of pancreatitis in cats is challenging. It is not known whether the high doses of corticosteroids usually used for cats with IBD have any deleterious effects on cholangitis and pancreatitis in cats with triaditis. The authors' clinical impression, based on limited experience, is that while this may produce short-term clinical improvements, the longer-term benefits are more questionable.

228.3 LYMPHOCYTIC CHOLANGITIS

228.3.1 Clinical Features

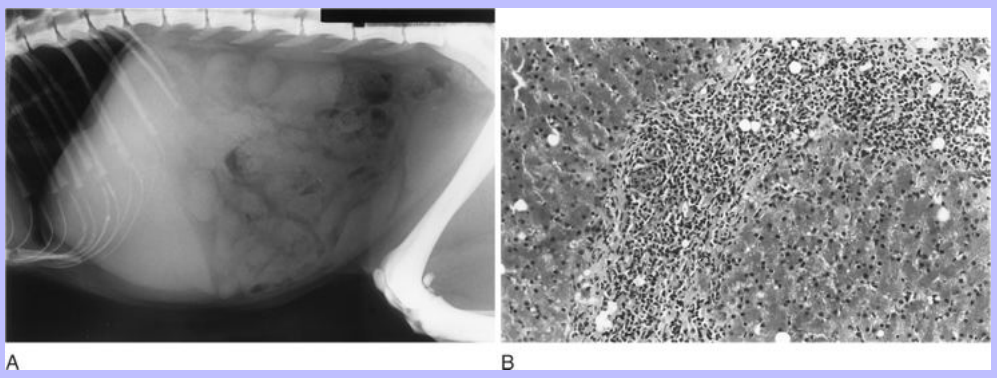
In contrast to suppurative cholangitis, lymphocytic cholangitis occurs more often in young cats, with more than 50% of cases in cats under 4 years of age.[5] A predisposition exists in Persian cats, but no sex bias is seen.[5] This form of inflammatory liver disease is seen much more frequently than suppurative cholangitis in the authors' clinic.

The etiology of this disease is unknown, although an immune-mediated mechanism is believed to contribute to the pathogenesis.

The two main presenting signs in lymphocytic cholangitis are (1) jaundice and (2) progressive ascites. 1451
Occasionally both clinical signs are present. In contrast to suppurative cholangitis, 1452 cats with lymphocytic cholangitis often do not appear ill. Appetite is often maintained and some cases show a noticeable polyphagia. There may be severe weight loss, but other cases retain reasonable bodily condition. It is unusual for pyrexia to be present. Hepatomegaly may be detectable on abdominal palpation, and in some cases this can be striking. Mild generalized lymph node enlargement is a common finding. This is most apparent on palpation of the

superficial lymph nodes but may also involve the mesenteric lymph nodes. In the later stages of the disease with extensive cirrhosis and portal hypertension, hepatic encephalopathy may develop.

Figure 228-2 **A** and **B,** Lateral radiograph of a cat with lymphocytic cholangitis showing severe hepatomegaly. Hepatic histology from the same case.



228.3.2 Diagnosis

An increase in liver enzymes (ALT, ALP, and GGT) and bile acids is usually seen that can be severe. Bilirubin levels may be increased, frequently corresponding with jaundice. Serum globulin levels are often raised, and this may reflect an increase in γ globulins detectable on serum protein electrophoresis. The most consistent change on hematology is lymphopenia. There may be some neutrophilia and mild anemia. If ascitic fluid is present, abdominal paracentesis will show this to be clear to yellow tinged. It is generally thick with a high protein content, the majority of which is globulin. The cellular content is generally low, with a nonspecific mixture of inflammatory cells.

Radiography may be complicated by the presence of ascites but may reveal hepatomegaly (Figure 228-2*A*). The liver may have a heterogeneous appearance on ultrasonography with irregular margins. If extensive cirrhosis occurs, the liver may have a hyperechoic appearance.

Histopathology is required to make a definitive diagnosis. Fine needle liver aspirates may reveal a lymphocytic infiltrate but will not show the characteristic changes in liver architecture, the location of the infiltration, or the pattern of fibrosis. Percutaneous core biopsy techniques generally provide diagnostic samples. However, the prominent presence of blood vessels on the surface of the liver, together with possible compromise of liver-dependent clotting factors, leads to a significant risk of postbiopsy hemorrhage; therefore biopsy at laparotomy provides the advantage of enabling better hemostatic control. Laparotomy also enables larger biopsies to be obtained, as well as selection of biopsy sites, including assessment and biopsy (if appropriate) of other abdominal organs.

The most important differential diagnoses for lymphocytic cholangitis are other causes of jaundice and ascites but particularly FIP and other liver diseases. The lymphadenopathy and preponderance of lymphocytes infiltrating the liver can potentially lead to confusion with lymphosarcoma, especially if needle aspirates are used, but can be differentiated on histopathology. Many similarities exist in the clinical and laboratory features of FIP and lymphocytic cholangitis—jaundice, ascites, raised liver enzymes, hyperglobulinemia, neutrophilia,

lymphopenia, and ascitic fluid with high globulin content. There may be pointers in the clinical presentation that may help to differentiate these two diseases, but this is complicated by the very variable clinical presentation of cats with FIP. Other features suggestive of FIP may be identified such as uveitis, neurologic signs, and pleural effusion. Reliable differentiation may depend on histopathologic investigations.

228.3.3 Treatment

Corticosteroids are the mainstay of treatment used based on countering immune-mediated damage to the liver. Considerable clinical experience supports their beneficial effect. Prednisolone is frequently used at an initial immunosuppressive oral dose of 1 to 2 mg/kg twice a day, which is gradually reduced over an extended period of 6 to 12 weeks according to the progress of the case. Other immunosuppressive agents are occasionally used (e.g., cyclosporine, chlorambucil, methotrexate, cyclophosphamide), but experience of their use and value is limited. Colchicine may be used at a dose of 0.03 mg/kg once a day in an attempt to combat fibrosis, although there have been no controlled trials to confirm any beneficial effect. Choleretics, SAMe, and nutritional support (see Suppurative Cholangitis) may be helpful. If ascites is severe, particularly if this is causing dyspnea due to pressure on the diaphragm, drainage by abdominal paracentesis may be indicated. Loop diuretics such as furosemide (1 to 2 mg/kg twice a day) combined with restriction of dietary salt may be helpful in mild ascites. Potassium-sparing diuretics (e.g., spironolactone) and angiotensin-converting enzymes (e.g., enalapril) are alternative agents for treating ascites.

1452 1453

Figure 228-3 Ultrasound of abdomen of a cat with suppurative cholangitis showing a dilated, tortuous bile duct.

228.3.4 Prognosis

Limited information is available about the prognosis for cats with lymphocytic cholangitis, but the majority of cats respond well to treatment. The mean survival in 25 cats in which portal hepatitis was described was 37 months, with 16 cats surviving for more than 1 year.[18] The authors' experience is that the prognosis is better in cats with jaundice compared to those with ascites. Lymphocytic cholangitis has been seen to resolve

spontaneously in occasional cases. Some cats will need repeated courses of prednisolone or may need to be maintained on long-term lower doses. Response to treatment is based initially on resolution of clinical signs. Monitoring of liver biopsies can be used to assess response to treatment but is usually declined by owners, and subsequent progress has to be based on monitoring laboratory features (particularly liver enzymes and bile acids).

228.4 MIXED INFLAMMATORY CHOLANGITIS

This form of cholangitis is seen less frequently and is less well characterized. It usually appears as a chronic disease with gradual loss of condition, although in some cases an initial episode of acute illness occurs with depression that may reflect acute suppurative cholangitis, leading to subsequent chronic liver disease. Jaundice is frequently present. The laboratory changes are similar to those seen in the other forms of cholangitis but are less consistent and frequently milder. The major dilemma in treatment of cats with cholangitis-involved mixed inflammatory infiltrates is whether antibiotics or corticosteroids are most appropriate for treatment. Limited experience suggests that the best response is achieved with prolonged corticosteroid treatment, but antibiotics are frequently administered in combination initially.

229 CHAPTER • 229 Vascular Liver Diseases

Kyle G. Mathews

Susan K. Bunch

229.1 EMBRYOLOGY AND ANATOMY

The portal vein is formed within the mesentery dorsal to the right limb of the pancreas by the confluence of the cranial and caudal mesenteric portal branches. It receives blood from the gastrointestinal (GI) tract and spleen via numerous mesenteric veins, the gastroduodenal, splenic, and gastric veins.[1] As the portal vein approaches the liver, it sweeps from right to left and divides into right and left branches, which further divide into branches supplying the individual liver lobes. The main right branch supplies the right lateral and caudate process of the caudate lobe, whereas the main left branch supplies all other lobes.[2] Within the hepatic parenchyma, the portal blood exits the portal triads, traverses the sinusoids, and ultimately enters the systemic circulation via the hepatic veins. The left hepatic vein is the only hepatic vein not hidden by hepatic parenchyma as it enters the caudal vena cava just caudal to the diaphragm.

Congenital extrahepatic portosystemic shunts (PSSs) are usually single vessels that connect the portal venous system to the systemic circulation, and as such may arise from any portal vessel. Most empty into the abdominal vena cava, but many will traverse the diaphragm prior to emptying into the thoracic vena cava or azygos vein. Intraoperatively, clinicians can easily locate most shunts by retracting the descending duodenum and examining the vena cava cranial to the left renal vein. If the shunt vessel is not located in this area, the surgeon retracts the liver to the right so that the esophageal hiatus may be examined for evidence of a portoazygous shunt. Occasionally, the omental bursa must be opened to gain access to shunt vessels dorsal to the stomach. This is done by tearing the ventral leaf of the greater omentum followed by cranioventral retraction of the stomach. Intraoperative imaging may be required in some cases to locate the shunt or to help make or exclude a diagnosis of microvascular dysplasia (MVD).

Many intrahepatic venous PSSs result from failure of the ductus venosus to close in infancy. Oxygenated blood from the placenta is carried from the left umbilical vein and umbilical sinus to the systemic circulation via the ductus venosus. It is not known why the ductus fails to close in some individuals. Pathology of the ductus wall or portal hypertension due to inadequate development of the portal venous tree has been speculated.[2] The cause of right-sided congenital intrahepatic and extrahepatic PSSs is unknown. Congenital extrahepatic PSSs are abnormal communications between the cardinal and vitelline venous systems.[3] Intrahepatic PSSs connect portal vein branches after their divergence from the portal vein proper to the hepatic veins or abdominal vena cava, thereby bypassing the hepatic sinusoids. They are usually hidden from view by the hepatic parenchyma. Left-sided shunts (patent ductus venosus [PVD]) arise from the left portal vein branch, pass through the left liver lobes or papillary process of the caudate lobe, and then empty into a venous ampulla cranial to the liver at its confluence with the left hepatic vein.[4,5] Central shunts pass through the right medial or quadrate lobes, and right-sided shunts pass through the caudate process of the caudate lobe or the right lateral liver lobe before emptying into the vena cava.[5,6]

Arterioportal fistulae (APF) are congenital vascular malformations that allow communication between the hepatic arterial blood supply and the portal venous system. The location of APF can vary; one or more lobes may be involved.[7–11]

229.1.1 Diagnostic Evaluation

229.1.1.1 History and Clinical Findings

For vascular anomalies that connect the portal venous system to the systemic venous system as the primary defect (i.e., single PSS, congenital mild diffuse or multifocal intrahepatic portovascular dysplasia), the signs, physical examination abnormalities, clinicopathologic changes, and certain histopathologic findings in liver biopsy specimens are directly related to diversion of portal blood flow around the liver. Intrahepatic portal pressure is normally higher than caudal vena cava pressure; therefore in the presence of a single patent anomalous conduit, portal blood flows preferentially around the liver. Exposure of the central nervous system (CNS) to shunted gut-derived toxins (e.g., ammonia and other encephalotoxins, absorbed bacteria, endotoxins) that would otherwise be removed by the liver results in signs of hepatic encephalopathy (HE), whereas lack of trophic factor-rich portal blood and oxygen (50% of that delivered) leads to poor hepatocyte growth and function.

In conditions that are characterized by high portal pressure (i.e., severe chronic hepatitis such as idiopathic noncirrhotic portal hypertension [NCPH] or single or multiple APF), previously rudimentary multiple extrahepatic shunt vessels connecting the portal vein with the caudal vena cava open to modulate portal pressure. These vessels are commonly found clustered around the left kidney, and occasionally in the submucosa of the esophagus, primarily in dogs and rarely in cats. Additional pathophysiologic consequences and signs of this acquired shunting are directly related to the underlying cause (e.g., high alanine transaminase activity in dogs with chronic hepatitis) and the existence of high portal pressure (e.g., ascites, GI bleeding).

229.1.1.1.1 Portosystemic shunt

Most cats and dogs with PSSs are examined because of signs of illness at less than 2 years of age,[12–28] but some animals have been 10 years of age or older at presentation.[14,15,27] Diagnosis may be missed in some individuals because the signs are subtle, or because owners believe that certain long-standing behaviors are “normal.” A gender bias has not been convincingly identified, although one study from Britain describing 45 dogs with intrahepatic PSSs reported that twice as many affected dogs were male as were female.[23] Male cats often outnumber females in the literature. A familial predisposition for single extrahepatic PSS is suspected in several small purebred dogs.[*] The inheritance pattern of PSS in Yorkshire terriers has been investigated through pedigree analysis and trial breeding, but it remains unclear.[25] A recent study that evaluated breed association in over 2000 dogs with vein-to-vein PSS in North America identified six breeds as having odds ratios near 20 or greater for having PSS: Havanese, Yorkshire terrier, Maltese, Dandie Dinmont terrier, Pug, and miniature schnauzer.[15]

Large purebred dogs, such as retrievers, Australian cattle dogs, Old English sheepdogs, and Irish wolfhounds, are more likely to have intrahepatic PSS.[*] PSSs are much less common in cats than in dogs.[20] As with small breed dogs, the majority of feline PSSs are congenital, single, and extrahepatic. Most cats with PSS are domestic shorthairs, but among purebred cats, the Himalayan and Persian are predisposed.[20,22,26] The history most commonly includes failure to thrive, neurologic signs that could include bizarre behavior such as yelping, staring, aggression, head pressing, and wall hugging, seizures, and intermittent blindness. These signs are usually present in cats by 6 months of age. Intermittent

ptyalism, which is a consistent finding in approximately 75% of cats, may be a subtle manifestation of GI disturbance or HE.[18,20,26,28] GI signs, including intermittent anorexia, vomiting, or diarrhea, are observed in about 30% of affected dogs[13] but less frequently in cats.[20,22,26] Anesthetic or sedative intolerance has also been recorded infrequently. Dogs that are older at the time of diagnosis can be presented because of polyuria-polydipsia (PU/PD), which has been reported to be associated with increased ACTH secretion and hypercortisolism,[29,30] or urate stone formation.[15,31]

Owners of affected dogs may remark that their pets have a dietary preference for fruits and vegetables. Onset of signs correlates with meal ingestion approximately 30% to 50% of the time. Some cats have a history of improved behavioral arid neurologic signs after antibiotic therapy.[12]

High portal pressure is not a feature of vein-to-vein vascular anomalies, so abdominal effusion does not form in animals with PSS unless they have profound hypoalbuminemia. Many cats are of small stature, poor body condition, and have an unkempt haircoat[12,14,20,22]; neurologic signs (e.g., amaurosis, dementia) and ptyalism may also be evident on examination. There may be evidence of other congenital defects; cryptorchidism was noted in about 30% of male cats in one study[20] and 50% of the male dogs in another study. Coexistent heart murmur has also been reported.[16,20,26] Bilateral renomegaly is seen in both species, and copper-colored irises inappropriate for the breed in cats may also be noted in dogs (Yorkshire terrier, Maltese, Dandie Dinmont terrier, pug, and miniature schnauzer).[15]

229.1.1.1.2 Mild diffuse or multifocal intrahepatic portovascular dysplasia

A disorder first described in 82 dogs and 23 in cats in which the signalment and signs resemble those of animals with PSS but a macroscopic vascular anomaly cannot be identified[32] has been termed microvascular dysplasia (MVD).[32,39] This condition can occur as the sole anomaly or jointly with PSS. Based on histopathologic changes in liver specimens and detailed portography, the anatomic site of vascular abnormality is believed to be the terminal portal veins. In Cairn terriers, MVD is believed to be an autosomal inherited trait; the specific mode of inheritance has not been established.[35]

The same dog breeds that are predisposed to PSS are those that have been described with MVD,[33,34,38,39] and cats are typically domestic shorthairs.[32] Common presenting signs include vomiting, diarrhea, and signs of HE, especially in dogs with both defects. Dogs with only MVD are somewhat older,[34,36] and many have mild to no signs of illness.

229.1.1.1.3 Idiopathic noncirrhotic portal hypertension

1454

A category of hepatopathies in human patients characterized by intra-abdominal portal hypertension, a patent portal vein, and relatively unremarkable liver biopsy findings has been described and termed noncirrhotic portal hypertension (NCPH).[40–44] Two unusual previously reported diseases of primarily young dogs (≤2.5 years) might be able to be grouped under this same name: *hepatoportal fibrosis* in 3 dogs[45,46] and *primary hypoplasia of the portal vein* in 42 dogs).[47] Two more recent reports describe a syndrome resembling idiopathic NCPH in four Doberman pinscher dogs,[48] three of which were related,

1455

and a similar condition in 33 dogs of various breeds.[49] NCPH has also been reported as an incidental finding in a colony of dogs with mucopolysaccharidosis Type I.[50] This condition is seen most often in purebred dogs 4 years of age or younger, of either gender, weighing over 10 kg. Individual cases had been described earlier but were buried in reports of PSS. Presenting signs include abdominal enlargement associated with effusion, GI abnormalities, polydipsia, weight loss, and less consistently, signs of HE. The cause for this group of conditions has not been identified, but the unifying thread amongst the theories is severe, diffuse intrahepatic vascular malformation. Dogs with NCPH have similar signs, clinicopathologic test results, and diagnostic imaging findings as dogs with cirrhosis, but they differ substantially in histopathologic changes in liver biopsy specimens and prognosis. This condition may represent severe diffuse or multifocal intrahepatic portovascular dysplasia.

229.1.1.1.4 Arterioportal fistulae

Clinical signs associated with APF are usually acute in onset during the first year of life and are primarily associated with the portal hypertension that results from conference of high-pressure arterial blood to the normally low-pressure portal venous system. Young medium to large breed dogs are most commonly reported, although small breeds may also be affected.[10] This appears to be a rare condition in cats.[51] Nearly all animals with APF have ascites[9,11,51,52] (Figure 229-1). Vomiting, diarrhea, lethargy, and weight-loss are also commonly reported.[8] Signs consistent with HE have been reported less frequently. In some animals with APF, the sound of turbulent blood flow through macroscopic fistula or fistulae, resembling the heart murmur in animals with patent ductus arteriosus, can be ausculted across the body wall over the affected lobe or lobes.

229.1.1.2 Clinicopathologic Test Results

Clinicopathologic findings in over 50% of affected dogs, regardless of the type of vascular anomaly, are typical of global hepatic dysfunction: hypoalbuminemia, euglycemia, hypoglycemia, hypocreatinemia, hypocholesterolemia, normal to low blood urea nitrogen (BUN) concentration, postchallenge hyperammonemia, and normal or high fasting with high postprandial serum bile acid (SBA) concentrations.[13,16,18,28] Clinicopathologic evidence of hepatic dysfunction eliminates the possibility of certain inborn errors of metabolism that cause hyperammonemia in young animals (e.g., urea cycle enzyme deficiency,[53] methylmalonic academia[54]) or hyperammonemia associated with urethral obstruction.[55] Target cells can be seen in some dogs, but microcytosis is the most common hematologic change in dogs; iron sequestration or ineffective iron transport have been proposed as causes for iron-deficient erythropoiesis.[56,57] Two to threefold increases in serum alkaline phosphatase (AP) and alanine aminotransferase (ALT) activities are commonly recorded; the origin of high serum AP activity is unknown. The AP isoenzyme of bone origin could be part of the high serum total AP activity in growing dogs, but subcellular hepatic organelle injury and increased release or decreased elimination of canalicular AP has also been proposed.[58] A study comparing dogs with intrahepatic PSS versus dogs with extrahepatic PSS made no particularly surprising discoveries; dogs with intrahepatic PSS weighed more and had higher blood glucose concentration and serum AP values than did dogs with extrahepatic PSS.[19]

Figure 229-1 Preoperative photograph of a typical puppy with an hepatic arterioportal fistula. Ascites has resulted in a pot-bellied appearance. Numerous catheters and monitors have been placed, including a cephalic venous catheter for fluid and plasma administration, arterial catheter to monitor blood pressure, and a jugular catheter to monitor central venous pressure (CVP). The patient is placed on a warm-air blanket to help prevent hypothermia. (Courtesy of Dr. Chick Weisse.)

Dogs with MVD may have similar but less dramatic changes as dogs with other vascular anomalies, but never have microcytic red blood cells (RBCs).[35–37,39] In fact, high SBA concentrations may be the only clinicopathologic finding in young purebred dogs with MVD that have been screened for PSS before sale or that are ill for nonhepatic reasons. The authors of one study attempted to distinguish dogs with MVD from dogs with MVD and PSS by use of a regression equation developed from four variables that were the most discriminating values in multiple regression analyses:

$$\begin{aligned}\text{diagnosis} = {} & 2.851 - (0.00135 \times \text{cholesterol concentration}) \\ & - (0.234 \times \text{albumin concentration}) \\ & (0.0209 \times \text{MCV}) + (0.000517 \\ & \times \text{postprandial SBA concentration}).\end{aligned}$$

Values approaching one were most consistent with a diagnosis of MVD and PSS, where values closer to 0 were likely associated with MVD alone.[36] Essentially, the lower the values for serum cholesterol and albumin concentrations, and MCV, and the higher the SBA concentration, the more likely the diagnosis of PSS.

In cats, poikilocytosis is common, and about 30% have erythrocytic microcytosis. Serum albumin, urea, and cholesterol concentrations can be strikingly normal or in the low-normal range. Serum glucose concentration is usually normal as are liver enzyme activities. The most consistent clinicopathologic abnormality in cats with PSS is high SBA, hyperammonemia, or both.[*]

As many as 50% or more of affected animals of both species may have dilute or hyposthenuric urine, but fewer numbers inconsistently have ammonium biurate crystalluria in a freshly voided and analyzed urine specimen. Persistent hyperammonemia and decreased ability to convert uric acid to allantoin favor

formation of ammonium urate uroliths independent of urinary pH,[63,64] which, in some cats and dogs with PSS, may be the only presenting complaint.[20,31] Rarely, bilirubinuria can be seen in the absence of other chemical or sediment abnormalities. Other than concentrating defects and urinary sediment findings typical of animals with hepatic vascular anomalies, little information is available concerning characteristic renal consequences. Arising from preliminary observations that a small group of dogs with PSS had glomerular sclerosis, renal tissue from 12 dogs with PSS that had died or were euthanatized was examined retrospectively.[66] In six of nine dogs in which urinalysis was done, trace to 1± protein by dipstick analysis was found. All 12 dogs however, had light microscopic evidence of glomerulopathy, with severity scores assigned as moderate to severe in nine of 10 dogs in which paraffin-embedded tissue was available. The renal changes were believed to be associated with shunted antigens from the GI tract; direct immunoperoxidase staining failed to consistently identify immunoglobulin deposition. Renal volume and glomerular filtration rate were compared with reference values in 21 dogs with confirmed PSS, with renal volume compared pre-and postsurgical correction in five dogs. Values for both decreased after surgery, perhaps explaining in part why many dogs with PSS are polydipsic before surgery and that this directly relates to the presence of shunting.[67] Primary polydipsia was also documented in three dogs with PSS and theorized to be another reason for increased water consumption.[68] In animals with abdominal effusion associated with NCPH or APF, fluid analysis is consistent with a pure transudate.

229.1.1.3 Hepatic Histopathologic Findings

Microscopic findings in liver specimens from dogs and cats with naturally occurring PSS mimic those of dogs with surgically created PSS, which was first described by Nicholas Eck in 1877.[69] Mild to moderate lobular hepatocellular atrophy with close approximation of portal venules, inconspicuous portal vein tributaries of small caliber, arteriolar duplication, lipidosis and vacuolar change, smooth muscle hypertrophy and increased lymphatics around central veins, and Ito cell hypertrophy are the findings in both species. Some animals have mild fibrosis around central veins. Minimal, if any, evidence of necrosis or inflammation is seen.[12,18,23,70–72] Random intralobular thin-walled blood vessels can also be seen and may represent a compensatory response to decreased portal blood flow. The histopathologic changes in the liver are considered identical in dogs with PSS, MVD, and NCPH,[32,35,37,39,47–50] and can be over-or misinterpreted among boarded pathologists (Table 229-1).

Histologic changes in liver tissue at some distance from the vascular malformation or malformations in animals with APF are similar to those of other vascular anomalies, presumably associated with portal blood deprivation.[9,11,52] Findings in liver tissue in close proximity to the fistula include dilated portal venules, marked arteriolar hyperplasia, and sinusoidal capillarization. Some portal veins in resected lobes manifest evidence of previous thrombus formation and recanalization.[9]

229.1.1.4 Diagnostic Imaging

Microhepatia is found on survey radiographs in about 50% of cats,[12,14,20] and 60% to 100% of dogs[15,17,18,36] with PSS. Bilateral renomegaly may also be documented. In dogs with MVD, the liver and kidneys are usually of normal size radiographically,[35,37] but the liver can be small in some cases.[36] Ammonium biurate uroliths are discovered in the bladder most commonly, but they can develop in the

kidney, urethra, or both. They can be radiolucent, but usually contain enough calcium salts and magnesium ammonium phosphate to make them moderately radiopaque.

Confirmation of vascular communication or communications between the portal system and the systemic circulation may be achieved by using a variety of imaging modalities including ultrasonography, nuclear scintigraphy, portography, computed tomography (CT), and magnetic resonance imaging (MRI).

Ultrasonographic evaluation of potential PSS is both sensitive (80% sensitivity for canine extrahepatic shunts, 95% overall for canine shunts) and specific (67% specificity for extrahepatic shunts, 98% overall).[6,73] It is less invasive than portography, doesn't require the licensure and handling precautions needed for administration of radioisotopes, and unlike CT does not require general anesthesia. Abdominal ultrasonography should therefore be strongly considered for all patients with possible PSS. Sensitivity improves with intrahepatic PSS (100%) as the shunt vessel is surrounded by hepatic parenchyma (Figure 229-2), whereas extrahepatic PSSs are generally smaller and may be obscured by sound wave attenuation "shadowing" secondary to the presence of gastric or intestinal gas.[6,73] The authors' experience with ultrasonographic evaluation of canine extrahepatic PSS suggests that results are highly operator dependent. The experience level of the operator must be taken into account when evaluating results. Origin and termination of the shunt vessel or vessels may be identified in many cases, but an understanding of the geometry and location of complex, tortuous shunts may be difficult to appreciate using two-dimensional ultrasonography. In patients with complex intrahepatic shunts, intraoperative ultrasonography may improve the surgeon's ability to locate and define the morphology of the shunt, although this has not been well described. Color flow and pulse wave Doppler ultrasonography offers the added advantage of visualization of blood flow direction, turbulence, and measurement of portal blood flow velocity. Portal flow velocity was decreased in dogs with experimentally induced cirrhosis with secondary portal hypertension and multiple extrahepatic shunts[74]; therefore it may also be decreased in dogs that develop multiple shunts secondary to naturally occurring liver disease or after surgical attenuation of shunt vessels. The normal portal flow velocity for dogs is around 15 cm/sec, and flow velocity and direction is relatively uniform. Portal flow velocity was increased or variable in 9/17 (53%) dogs with a congenital extrahepatic shunt, and in 12 of 13 (92%) dogs with an intrahepatic shunt. Increased flow velocity may be due to decreased resistance to cranial flow because of the presence of the shunt.

1456 1457

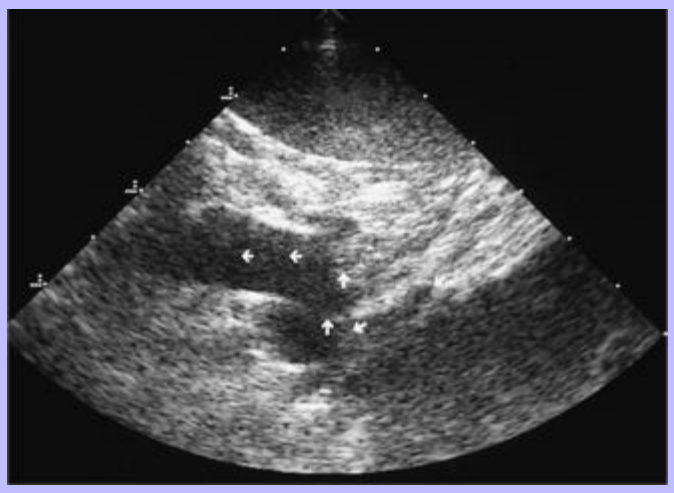
CPS, Portosystemic venous shunt; *MVD*, microvascular dysplasia; *NCPH*, noncirrhotic portal hypertension; *N*, normal.

Figure 229-2 Sonogram of an intrahepatic portosystemic shunt surrounded by hepatic parenchyma. The arrows indicate direction of blood flow determined by color flow Doppler ultrasonography. (Courtesy of Dr. Kathy Spaulding.)



A variety of rectally administered radiopharmaceuticals have been used to identify the presence of PSSs.[76–79] ^{99m}Technetium pertechnetate is most commonly used because it is rapidly absorbed, relatively inexpensive, and has a short half-life.[76,79,80] After absorption by the colonic mucosa, ^{99m}technetium enters the colonic venous (portal) circulation and is transported cranially to the liver. The patient is placed in right lateral recumbency on the surface of a gamma camera, which detects the location of the isotope. This information is displayed on a computer monitor. In dogs with normal portal circulation, the liver is visualized as a bright area on the monitor as the isotope is initially delivered to the hepatic microcirculation (Figure 229-3). With time, the isotope enters the hepatic veins, caudal vena cava, and cardiopulmonary vasculature at which time the heart can be visualized on the monitor.

Although special handling of the isotope and patient are required, the study may be performed in less than 5 minutes and requires only light sedation. Morphology, number, and location of PSSs, if present, often cannot be ascertained using scintigraphy. By drawing regions of interest (ROI) around the liver and thorax using computer software, an estimate of shunt fraction is calculated based on the counts per pixel within each ROI (Figure 229-4). Normal dogs have a shunt fraction less than l5% (i.e., the image of the liver is significantly more intense than that of the thorax at the time of image acquisition).[81] In contrast, in animals with PSS the image of the heart is initially more apparent as the isotope bypasses the liver via the shunt (see Figure 229-3). Shunt fractions in dogs with macrovascular intra-and extrahepatic shunts often exceed 80%, whereas the reported mean shunt index for five cats was only 52% in one study.[82] The range of shunt fractions for dogs with MVD is thought to be lower than those with macrovascular shunts, although this has not been reported. Shunt fraction estimation is inexact and prone to inter-and intraoperator variability.[83] As such, changes in shunt fraction over time should be cautiously interpreted. Despite its limitations, per rectal scintigraphy is quite useful in determining if significant shunting is present. If ultrasonography has failed to

1457

1458

identify the presence of a shunt, yet clinical signs or laboratory test results are consistent with shunting, then scintigraphy should be considered.

Figure 229-3 Lateral per rectal technetium scintigrams. The head is to the right. Colonic technetium deposition site (*C*), liver (*L*), and thoracic (*T*) regions of interest. Technetium reaches the liver prior to the thorax in a normal dog (*top*). The situation is reversed in a dog with a portosystemic shunt (*bottom*).

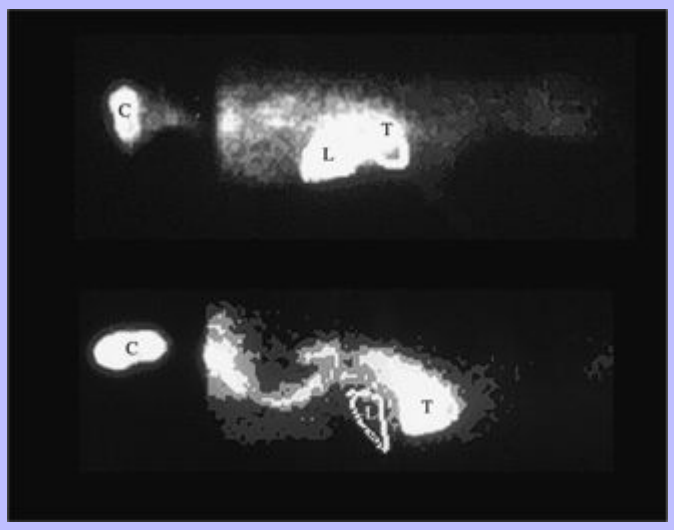


Figure 229-4

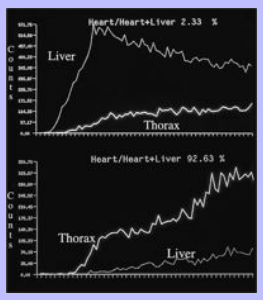


Time (seconds)/radioactivity (counts) curves of the normal (*top*) and shunt dog (*bottom*) depicted in Figure 229-3. Radioactivity in the liver is greater than that in the thorax in the normal dog (*top*). The situation is reversed in the dog with a portosystemic shunt (*bottom*). Shunt fraction is calculated by using data collected over 12 seconds starting at the separation of the curves using the formula:

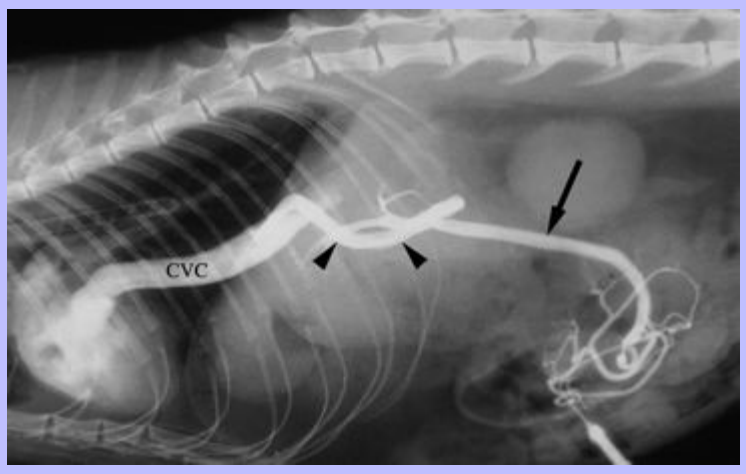
[Σ total heart counts over time]/[Σ(total heart counts) + (total liver counts) over time].

Shunt fraction was 2.3% in the normal dog and 92% in the dog with a shunt.

Portography, although less commonly performed because it is more invasive than ultrasonography and scintigraphy, has the advantage of offering a “global snapshot” of the patient's portal circulation. By injecting contrast medium into the portal circulation, the relative location and number of PSSs may be identified with fluoroscopy, plain radiography, or CT (Figure 229-5).[84] Percutaneous splenoportography may be performed preoperatively by injecting contrast into the splenic parenchyma with or without ultrasound guidance. Caudally located shunts may be missed with this technique. Injection of contrast medium into the mesenteric artery via a femoral artery catheter is now rarely performed because of less invasive options and because it results in a poorer quality study due to dilution as the contrast medium passes from the intestinal arterial to the portal circulation. Alternatively, a fluoroscopically guided catheter may be inserted in the right jugular vein and advanced into the caudal vena cava, shunt, and portal system in dogs with large intrahepatic shunts prior to insertion of thrombotic coils (see discussion of treatment of intrahepatic shunts), or it may be used in the minority of dogs in which the results of ultrasonography and scintigraphy are inconclusive or discordant.[85,86] Portographic imaging may be used intraoperatively by catheterization of a mesenteric or splenic vein to evaluate the morphology of the portal vasculature, to confirm the location of hard to find macrovascular shunts, or to rule out their presence in dogs suspected of suffering from MVD.[34,35,38,87,88] The same catheter is used to measure portal pressures during shunt manipulation. Intraoperative portography can be cumbersome, because it requires either a portable radiographic unit or temporary closure of the abdominal incision and transport of the patient. Sensitivity of intraoperative portography has been reported to be between 85% and 100% and is dependent on patient positioning.[89]

Computed tomography (CT) is primarily performed in dogs with complex intrahepatic shunts. Contrast medium injected into a peripheral vein highlights both the systemic and portal venous circulation. Alternatively in large dogs, the contrast medium may be injected into a splenic vein using ultrasound guidance.[90] Because the radiopacity of the vasculature changes rapidly, helical CT is preferred because it allows rapid acquisition of data over a large anatomic area.[91,92] Transverse images of the liver and its vasculature are then reconstructed after data acquisition. Three-dimensional images of the shunt created with specialized computer software are especially useful to surgical planning. Disadvantages to CT are the need for general anesthesia and the cost. A second anesthetic event may be eliminated if the CT scan is performed immediately prior to surgery; however, this allows the surgeon little time for evaluation of the images, especially if three-dimensional reconstruction is contemplated.

Figure 229-5 Lateral intraoperative mesenteric portogram of a cat. A large extrahepatic shunt vessel (*arrowheads*) originates from a branch of the portal vein (*arrow*) and terminates at the caudal vena cava (*cvc*). (Courtesy of Dr. Daniel Brockman.)



Two- and three-dimensional magnetic resonance angiography (MRA) have been reported as reliable techniques for evaluating shunt vessels in human patients.[93] Two-dimensional MRA, without contrast enhancement, has been evaluated in dogs with shunts and found to have the following sensitivities and specificities: multiple extrahepatic shunts (63% to 97%)[94] and single congenital shunts (79% to 97%). The use of gadolinium-enhanced and three-dimensional MRA as preoperative planning tools for animals with complex shunt anatomy has not been reported to date.

APF are seen as numerous tortuous vascular communications with ultrasound or celiac arteriography (Figure 229-6).[11] Microscopic hepatic arteriovenous fistulae were suspected in one young dog.[52] Ultrasonographic evidence of reversed portal blood flow (hepatofugal flow) and diminished forward (hepatopetal) flow are present in all cases. The portal venous system is often markedly distended. Multiple acquired PSSs may develop as a compensatory mechanism to diminish portal blood pressure and protect against splanchnic congestion (Figure 229-7).[9,11] Multiple shunts are most easily imaged in the region of the left kidney.

229.1.1.4.1 Differential diagnoses

If an animal suspected of having PSS is older than average at presentation, or if a young dog has signs of portal hypertension, other primary hepatopathies must be considered, such as chronic hepatitis; liver biopsy is needed. If a PSS cannot be identified by ultrasonography, transcolonic scintigraphy, surgery, or portography in a dog (or less commonly, a cat) suspected of having PSS, MVD is likely. Liver biopsy in such cases would provide evidence to exclude a more serious hepatopathy.

If APF are not found in a young dog with ascites, a normalized to small liver and clinicopathologic evidence of hepatic dysfunction, lobular dissecting hepatitis (or other form of chronic hepatitis), and NCPH are possibilities. Histopathologic examination of liver tissue will distinguish these disorders. An algorithm to facilitate diagnosis of vascular disorders in dogs and cats is provided in Figure 229-8.

229.1.2 Surgical Management

229.1.2.1 Preoperative and Operative Considerations

Clinicians have good reason to believe that signs of HE should be controlled before surgical correction is attempted. In one study, asymptomatic dogs had a better prognosis for complete recovery after surgery. To start, a diet moderately restricted in protein (minimum 20% on a dry matter basis [2 g protein/kg/day] for dogs; 30% on a dry matter basis [3 g crude protein/kg/day] with adequate amounts of taurine and arginine for cats) is recommended.[95–98] If signs are not controlled with dietary modification alone, an oral disaccharide (e.g., lactulose, lactitol), antibiotics, and soluble fiber may be added. For animals with ascites secondary to portal hypertension, a diet that is moderately restricted in sodium (0.20% to 0.25% on a dry-matter basis) is beneficial.

After a diagnosis of PSS has been made, many clinicians prefer to preload patients with PSS on anticonvulsant medications to diminish the risk of postoperative seizure activity. Potassium bromide (dogs: 100 mg/kg, orally every 24 hours; cats: 30 mg/kg, orally every 24 hours) may be started 2 weeks prior to surgery, and the dose adjusted (30 to 100 mg/kg, orally every 24 hours) to obtain a serum concentration of 100 to 200 mg/dL.[99] The lower end of the dose should be used in cats, because many develop coughing as an adverse effect.[100] Similarly, phenobarbital may be started (2.2 mg/kg, orally every 12 hours) and the serum concentration evaluated prior to surgery. Oral lactulose, antibiotics, and a low-protein diet are generally started at the same time.

Given that most animals undergoing surgical correction of a PSS are hypoalbuminemic, and because current methods used to detect diminished hepatic production of clotting factors are insensitive (e.g., prolonged PTT), fresh frozen plasma is commonly administered pre-and intraoperatively (6 to 10 ml/kg, intravenously).[101] Dextrose-containing fluids should also be considered in the perioperative period. Anemia combined with intraoperative fluid loading and blood loss may result in the need for cross-matching and blood transfusions.

Intraoperative portography may be needed if the macrovascular shunt is difficult to locate, or if MVD is suspected and macrovascular shunting needs to be ruled out.

Placement of a jugular catheter preoperatively is recommended so that central venous pressure (CVP) can be monitored during shunt attenuation and postoperatively.[102] An arterial catheter is also helpful in many cases for monitoring blood pressure.

Without intraoperative warming, PSS shunt patients are at risk for developing profound hypothermia. Fluid-line warmers, warm-air devices, heating blankets, or a combination of these devices should be used in all cases.

Patients undergoing surgical correction of an intrahepatic shunt may require additional surgical exposure cranial to the liver. A partial median sternotomy and diaphragmatic incision may need to be performed. In these cases, placement of a chest tube will be required prior to surgical closure.

229.1.3 Correction of Extrahepatic Portosystemic Shunts

Many extrahepatic PSSs (48% to 68%) cannot be completely occluded with a single surgery without causing life-threatening portal hypertension.[102–104] Once the shunt has been surgically identified, surrounding tissues are dissected away as close to the vena cava or diaphragm as possible (Figure 229-9). A suture is passed around the shunt so that temporary occlusion may be performed while measuring portal pressures. A variety of parameters are then evaluated during temporary occlusion to determine if complete ligation of the vessel is prudent. Significant increases in portal pressure as measured by a manometer attached to a catheter placed within a jejunal vein, increased intestinal peristalsis, intestinal and pancreatic venous congestion, and decreases in CVP are all indications that complete occlusion should not be attempted.[102,105] Perioperative mortality rates after partial or complete ligation are generally between 10% to 20%.[13,28,103,105] Most dogs with a partially ligated shunt vessel improve clinically and often can be taken off of symptomatic treatment for some time. However, up to 41% to 50% of animals with partially ligated extrahepatic shunts redevelop clinical signs months to years postoperatively (mean: 3 years).[28,103,106] Because of this, repeat laparotomy to attempt complete ligation, before clinical signs recur, has been recommended. Parameters to determine appropriate timing for reoperation have not been documented. Of 24 dogs that underwent partial occlusion of their extrahepatic shunt, complete shunt occlusion occurred spontaneously in 15 (63%) 1 to 6 months postoperatively.[107] This would argue against repeat surgery within this time period.

Staged or gradual occlusion of the shunt vessel can result in complete resolution of shunting in many animals. By placing materials around the shunt that result in its gradual closure, acute portal hypertension associated with complete ligation may be avoided and perioperative mortality diminished. In addition, multiple surgeries are not required. Two implantable materials (ameroid rings and cellophane bands) have been evaluated for this purpose. Ameroid rings are composed of hydrophilic casein that swells over time (Figure 229-10). They are surrounded by a stainless steel collar, which limits outward expansion. They were originally designed as a cardiovascular research tool to create gradual occlusion of coronary and other vessels and have been adopted as a treatment tool by veterinary surgeons. Placement around a shunt vessel results in occlusion in 30 days in most animals, although delayed closure of up to 90 days has been reported.[72] Shunt occlusion has been thought to be due partly to ring swelling, and partly due to an inflammatory reaction with fibrosis around the ring. The mechanisms by which the portal circulation accommodates increased flow have not been reported, but it is clear that acute increases result in life-threatening portal hypertension, whereas gradual increases in portal flow lead to increased liver size. Portal hypertension associated with sudden complete shunt occlusion is generally not a problem after ameroid ring placement unless the weight of the ring kinks the vessel postoperatively, or excessive manipulation of the shunt vessel during ameroid placement results in thrombotic shunt occlusion.[72] A recent study investigating ameroid ring placement on external iliac veins in six dogs showed that the luminal area of the ring only decreased by 23%. All dogs had evidence of venous thrombosis at the site, with complete occlusion occurring by the sixth day in half of the dogs.[108] This rate of PSS occlusion after ameroid placement may be too rapid, and could theoretically result in subclinical portal hypertension and subsequent development of multiple extrahepatic PSSs. Multiple acquired shunts have been reported in approximately 10% to 20% of dogs, and are even more common in cats, after ameroid placement (see Feline Portosystemic Shunts: Unique Considerations).[72,109] In these patients, symptomatic treatment may

need to be continued indefinitely. It is interesting to note that four of 24 dogs (17%) < in one study that had an extrahepatic PSS partially ligated) also went on to develop multiple acquired shunts despite continued flow through the original shunt.[107]

Figure 229-8 Suggested diagnostic path for animals suspected of having a portovascular anomaly.

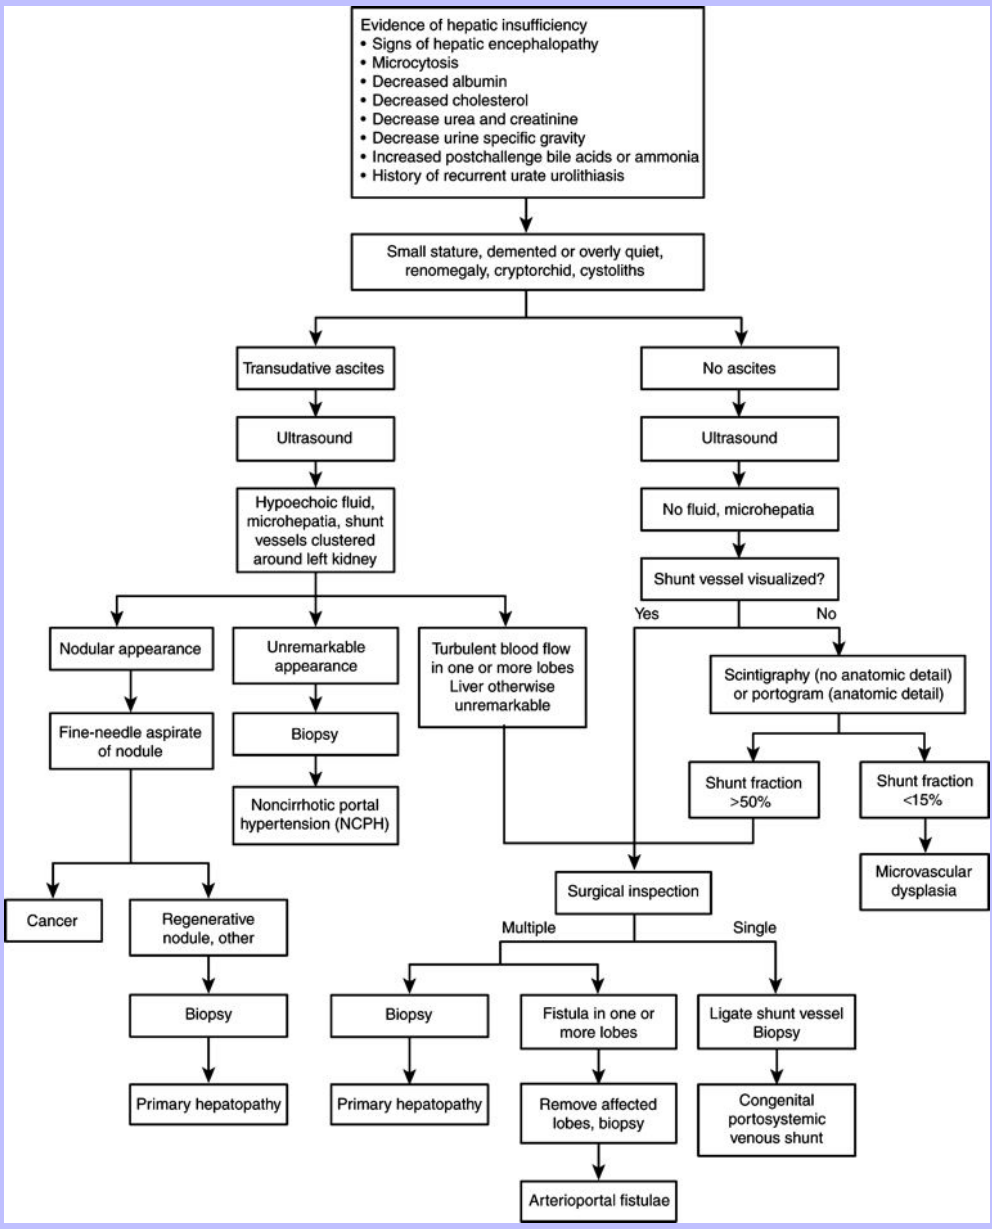

Figure 229-9 Intraoperative photograph of a large splenic vein to abdominal vena cava portosystemic shunt vessel (*arrow*). (Courtesy of Dr. Chick Weisse.)

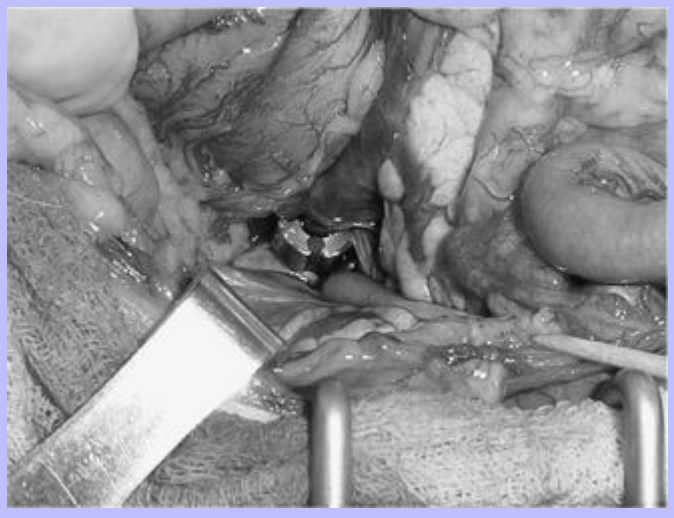
Figure 229-10 Intraoperative photograph of the same PSS seen in Figure 229-5 after placement of an ameroid ring around the vessel. (Courtesy of Dr. Chick Weisse.)



An alternative to the ameroid ring is cellophane tape or film, which is derived from plant cellulose. Cellophane incites an inflammatory reaction that results in gradual attenuation of the shunt vessel. Progressive occlusion is slower and potentially less complete than with ameroid constrictors; however, potentially diminished risks are associated with placement, including less risk of tearing the shunt, less shunt manipulation required, and less risk of kinking the shunt postoperatively. Additionally, because occlusion is slower, there may be a diminished risk of developing multiple acquired shunts. When placed around the femoral vein in six dogs occlusion was progressive over a 6-week period in four of six dogs, and was incomplete in all.[110] Of eleven dogs with extrahepatic PSSs treated with cellophane banding, 10 had resolution of shunting. In eight dogs, shunt occlusion occurred by 8 weeks, whereas occlusion did not occur until 7 and 11 months in the remaining two dogs.[111]

229.1.3.1 Correction of Intrahepatic Portosystemic Shunts

Intrahepatic shunt vessels are hidden from the surgeon by hepatic parenchyma in most cases. Because of their large diameter, complete ligation is rarely accomplished with one surgery. The location of the shunt may be confirmed intraoperatively by a variety of means. Palpation of the liver will often reveal a soft spot with accompanying fremitus in the affected liver lobe. Intraoperative mesenteric portography or ultrasonography may also be performed.[112] The portal vein branch that feeds the shunt vessel, as well as the exit point of the shunt, can be identified by passing a catheter through a purse-string suture and small incision in the portal vein. The catheter is passed cranially through the shunt and into a prehepatic venous ampulla or thoracic caudal vena cava. A left-sided shunt (PDV or patent ductus venosus) empties into a venous ampulla, which also receives the LHV prior to emptying into the vena cava at the level of the diaphragm.[113] The shunt vessel, LHV-ampulla, or both are bluntly dissected free from the surrounding tissues between the liver and the diaphragm. The shunt vessel, LHV-ampulla, or both are then either partially ligated while monitoring portal venous pressures, or a large ameroid constrictor or strip of cellophane is placed.[114] Experimental occlusion of the LHV in normal dogs resulted in transient congestion of the left and central hepatic lobes, but it had no clinical effect.[115] New information indicates that dissection and partial ligation of the LHV or ampulla is not needed because left-sided shunts may be dissected prior to their entry into the ampulla in most cases.[5] If the shunt vessel empties directly into the vena cava (most right-sided and central shunts), a determination is made as to whether the portal vein branch that feeds the shunt can be dissected free from the surrounding tissues.[116,117] If possible, partial ligation, ameroid ring or cellophane band placement on this vessel is performed.[118] Shunt vessels that empty directly into the vena cava, and for which the feeding portal branch cannot be isolated, are either partially ligated after inflow vascular occlusion of the liver, or an extrahepatic shunt may be created by placing a jugular vein graft or grafts between the portal vein and abdominal vena cava. After graft placement, complete resection of the shunt and its surrounding liver lobe has been reported. Inflow vascular occlusion of the liver requires that the patient or liver be hypothermic at the time of surgery to limit ischemic damage to the liver. Whole body hypothermia has been reported in dogs with good results, despite complications that include severe hypotension, arrhythmias, acidemia, and cardiac arrest secondary to increased myocardial irritability.[119] Topical cooling of the liver with cold saline may protect it from ischemia and reperfusion injury without the systemic side effects seen with whole-body hypothermia; however, this has not been evaluated in dogs with PSS.[120] To perform inflow occlusion, the aorta (or celiac and cranial mesenteric arteries), portal vein, and abdominal and thoracic vena cava are temporarily occluded. This allows the surgeon to make an incision into the thoracic vena cava or the portal vein,

1461

1462

identify the shunt, and place a circumferential suture around it.[116,121] Once the venotomy has been closed and blood flow to the liver has been reestablished, the circumferential ligature is slowly tightened while monitoring portal pressures as for extrahepatic shunts. The significant blood flow through large intrahepatic shunts cannot be suddenly obstructed by the surgeon without the development of life-threatening portal hypertension. Intraoperative shock (hemorrhagic and septic), cardiac arrest, and portal hyper-and hypotension have been listed as causes of intraoperative death. Postoperative survival rates vary from 75% to 89%, with peritonitis, portal vein thrombosis, and portal hypertension listed as the most common causes of death in the postoperative period.[17,19,23,28,116] Predictors for the development of postoperative complications were low body weight (<10 kg) and hypoproteinemia or hypoalbuminemia in one study.[122] Shunt location had no effect on short or long-term outcome. One-and 2-year survival rates were 60% and 55%, respectively, for partially attenuated shunts. After 4 months, euthanasia because of failure to show clinical improvement, was the most common cause of death. Another study followed 37 dogs that survived initial intrahepatic PSS attenuation. Twenty-eight (76%) became clinically normal and required no medical management (mean follow-up: 16 months).[23] Nine dogs had persistent or recurrent encephalopathy of which three were euthanized without surgery. Six dogs were reoperated, three successfully ligated, and three euthanatized at surgery.

Complete occlusion requires multiple-staged procedures, unless a vein graft is placed between the portal vein and the vena cava. By placing the graft, portal hypertension may not develop after complete occlusion of the intrahepatic shunt. Splenectomy followed by anastomosis of the splenic vein to the abdominal vena cava has been used to alleviate portal hypertension in one dog as an emergency procedure.[123] Intraoperative hemorrhage from an intrahepatic PSS in this dog necessitated resection of the involved liver lobe and created life-threatening portal hypertension. As a planned procedure, a jugular vein may be harvested and used to create a bridge between the portal vein and the abdominal vena cava. With this technique, the surgeon essentially moves the shunt to an extrahepatic location, which allows for ligation or resection of the intrahepatic shunt. This new extrahepatic shunt can then be treated by placing an ameroid constrictor around the graft in an attempt to achieve complete resolution of all portosystemic shunting. This technique has been reported in a limited number of cases.[124,125] Eight of 10 dogs could have their intrahepatic PSS completely ligated using this technique in one study.[124] Nine of these dogs had an excellent clinical outcome, despite the development of multiple PSS in four of eight dogs reevaluated 8 to 10 weeks postoperatively.

Given the invasiveness and complexity of surgical correction, interventional radiologic techniques may become more routinely performed in the future. Transjugular coil embolization of canine intrahepatic PSS has been reported, and the short-term results are promising.[86,126] A fluoroscopically guided catheter is advanced from the right jugular vein to the caudal vena cava and shunt vessel. Contrast studies and measurement of portal pressures before and after coil placement are performed. A cylindric wire mesh stent is placed in the caudal vena cava at the level of the shunt to prevent coil migration. Catheter-delivered thrombogenic coils are then placed in the shunt (Figure 229-11). Complete or near complete occlusion of the shunt requires multiple-staged coiling sessions to prevent the development of acute portal hypertension.

229.1.3.2 Feline Portosystemic Shunts: Unique Considerations

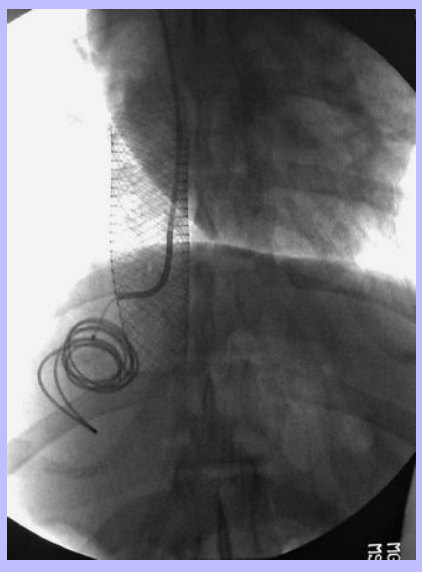
Complete ligation of feline PSS is only possible in one of three cases. Most importantly, the prognosis after partial surgical ligation is less favorable than that reported for dogs. Although clinical improvement is usually seen after surgery, only 57% of 22 cats had a good to excellent long-term outcome.[60] Persistence or

recurrence of clinical signs has been reported in the majority of partially ligated cases.[12,20,59–61] For this reason, staged attempts to completely ligate the shunt vessel are advocated,[20,24] with resolution of clinical signs possible if complete ligation is eventually achieved.

Given the poorer prognosis associated with partial ligation when compared with dogs, gradual occlusion of feline PSSs with ameroid constrictors has also been investigated.[25,62] After ameroid placement, many cats (33% to 77%) experience postoperative complications, including central blindness (zero to 45%), hyperthermia (zero to 27%), seizures (8% to 14%), and frenzied behavioral changes (zero to 23%). Most of these complications are temporary. It should be noted that postoperative hypothermia and hypoglycemia are commonly reported in studies evaluating feline response to PSS ligation. Despite the high frequency of complications, the postoperative mortality rate is low (zero to 4%) and compares favorably to surgical attenuation (complete or partial ligation) of feline PSS (11%).[20] However, at recheck evaluation 8 to 10 weeks postoperatively, persistent shunting is common (57%). This is most likely due to the development of subclinical portal hypertension resulting in multiple acquired extrahepatic shunts, although this has been documented in only a few cases. As with dogs, too rapid closure of the shunt vessel or an underdeveloped portal system (or both) may contribute to portal hypertension. Long-term results vary between studies with 33% to 75% of cats reported as having a good to excellent clinical outcome[25,62] and 18% to 66% having a poor outcome. Owners contemplating surgical treatment for their cats' extrahepatic PSSs should be made aware of the discordant results reported in the current literature.

1462
1463

Figure 229-11 Ventrodorsal fluoroscopic image of a catheter-delivered thrombogenic coil being placed into a large right-sided intrahepatic portosystemic shunt (PSS). The dog's head is toward the top of the image. A cylindric braided wire stent has been placed in the caudal vena cava at the level of the diaphragm to prevent cranial migration of the coil. (Courtesy of Dr. Chick Weisse.)



Fewer than 10% of feline shunts are intrahepatic, and acquired shunts are rarely reported, therefore less can be said regarding their long-term prognosis.[20,127] A left-sided intrahepatic shunt consistent with a PDV is most common, although shunts involving the right and central liver lobes have been reported. As in dogs, feline PDVs empty into a venous dilatation or ampulla that receives contributions from the PDV, left hepatic veins, and phrenic veins prior to emptying into the caudal vena cava at the level of the diaphragm.[128,129] Partial ligation of the intrahepatic shunt cranial to the hepatic parenchyma has been reported in 10 cats.[129] Most cats survived these procedures.[70,128,129] Complete occlusion of the shunt by ligation of the portal vein branch feeding the shunt and transjugular coil embolization has been reported in one cat each.[70,130] Both cats survived and were clinically normal at long-term follow-up. This is in contrast to canine intrahepatic shunts, which can rarely be completely occluded with a single procedure.

229.1.3.3 Correction of Arterioportal Fistulae

Surgical treatment by resection of the affected liver lobe is successful in the majority of cases that have not gone on to develop multiple shunts. Partial hepatectomy has been successfully performed with and without temporary occlusion of the hepatic vasculature.[7,8,10] Portal hypertension resolves immediately after liver lobectomy, although this resolution is incomplete in many cases.[7,8,10] After surgery, animals that have formed multiple shunts may need to be treated medically with low-protein diets and medications as previously discussed for other forms of portosystemic communications. Upon review of 11 dogs with APF from four reports, eight of the dogs had developed multiple shunts by the time of surgery.[7,10,131,132] Two dogs died or were euthanized at surgery; one died 15 hours postoperatively (hypovolemic shock); one dog each was euthanized at 1 month (esophageal stricture), 14 months (recurrent hepatoencephalopathy), 26 months (hemorrhagic diarrhea), and 31 months (recurrent vomiting). Four of the 11 dogs (36%) were still alive at 5, 24, 26, and 36 months postoperatively. One dog still suffered from episodic HE 24 months postoperatively; the others were reportedly normal and off all medications and dietary management.

229.1.3.4 Multiple Acquired Portosystemic Shunts

Multiple acquired shunts form in response to increase portal blood pressure. Cirrhosis, APF, and NCPH are some conditions that may result in formation of multiple shunts (see Figure 229-11). Treatment is aimed at controlling the underlying problem if possible, and the prognosis is guarded unless the underlying problem can be ameliorated (see discussion of symptomatic treatment of PSS). Surgical treatment has been performed in the past by partially occluding the abdominal vena cava in an attempt to raise caval pressures above portal pressures and thus eliminate portosystemic shunting. Long-term survival and quality of life were no different between medically managed and surgically managed groups after hospital discharge in one study.[133] There appears to be no place for vena cava banding in animals with conditions causing portal hypertension.

229.1.3.5 Postoperative Complications

Despite preloading with anticonvulsants, postoperative seizure activity can still occur in PSS in some patients regardless of the shunt type or the surgical procedure performed.[134–138] Other residual neurologic deficits, such as transient blindness in cats, have also been reported.[62] In some cases, life-threatening status epilepticus may develop up to 3 days postoperatively. Some reports suggest that older animals are more

prone to developing this complication,[135,137] but this complication may occur regardless of age.[139] A few of the causes that have been suggested include alterations in brain amino acid and neurotransmitter profiles, and withdrawal of gut-derived benzodiazepine agonists.[140–142] Postoperative seizures in these patients appear to be most responsive to intravenous barbitutate[134] or a continuous rate infusion (CRI) of propofol (0.01 to 0.25 mg/kg/mm),[136] and management may require ventilatory and parenteral nutritional therapy.

Life-threatening portal hypertension is uncommon, but it may develop in the early postoperative period.[36,72,102,103] Clinical signs may include abdominal pain, hypotension, ascites, and vomiting. Reoperation to remove the suture or ameroid ring that is obstructing blood flow through the shunt vessel must be performed immediately. Successful outcome after reestablishment of shunt patency is uncommon.

Portal vein thrombosis may occur after shunt manipulation regardless of the surgical procedure.[105,143,144] Potential contributing factors to this condition include portal venous stasis or turbulent flow, endothelial damage, and hypercoagulability.[144] The authors have seen this occur in both dogs and cats with both intra-and extrahepatic shunts. Increases in portal venous pressures may result in the development of multiple shunts and continuation of clinical signs, or they may be severe enough to result in life-threatening GI venous stasis. The optimal method and duration of treatment is not clear. Treatment with anticoagulants, thrombolytic compounds such as tissue-plasminogen activator,[145] or both should be considered.

229.1.4 Treatment for Animals with Nonsurgical Conditions

For dogs with partially occluded PSS, inoperable PSS, NCPH, or for animals with owners who decline definitive treatment, symptomatic management is recommended for life. Quality of life is improved temporarily, but fluctuating neurologic signs and occurrence of urate urolithiasis can be expected. The current ability to manage clinical signs in dogs with congenital PSS primarily with diet is limited unless a purified diet is used, but it is no substitute for surgical correction. In a study of the long-term effects of surgically created end-to-side portocaval shunts in adult dogs, the diet used was a purified, carbohydrate-based diet formulated with a specific ratio of branched chain amino acid to aromatic amino acid composition. Both dogs with created portocaval shunt and sham-operated dogs lived comfortably for nearly 1 year, free of signs of HE and weight loss. These diets are not made commercially, so they are inaccessible to owners. Another study evaluated 23 dogs with congenital PSS that did not have corrective surgery but had symptomatic treatment for at least 3 years.[147] About half of the dogs had been euthanatized within 1 year of diagnosis, mostly because of uncontrollable HE, but nine dogs lived a reasonable quality of life for 3 to 8 years. Similar studies have not been performed in cats. Despite these encouraging findings in dogs, hepatic deterioration associated with poor portal blood flow progresses as long as the abnormal vascular pattern persists. The same regimen is used for cats with inoperable PSS or for cats whose owners decline surgery.

1463

1464

No surgical remedy for MVD exists, so symptomatic management for HE (if present) is the only treatment recommended. Affected dogs seem to live comfortably in good to excellent condition for at least 5 years without serious consequences.[25]

For dogs with NCPH, one study concluded that affected dogs might live as long as 9 years after diagnosis with minimal symptomatic treatment for ascites, and for some, HE. Four dogs were euthanatized because of problems related to persistent portal hypertension (e.g., duodenal ulceration, urate urolithiasis).[49]

For treatment of animals that have acquired portosystemic shunting associated with primary hepatobiliary disease, see elsewhere in this text.

230 CHAPTER • 230 Toxic, Metabolic, Infectious, and Neoplastic Liver Diseases

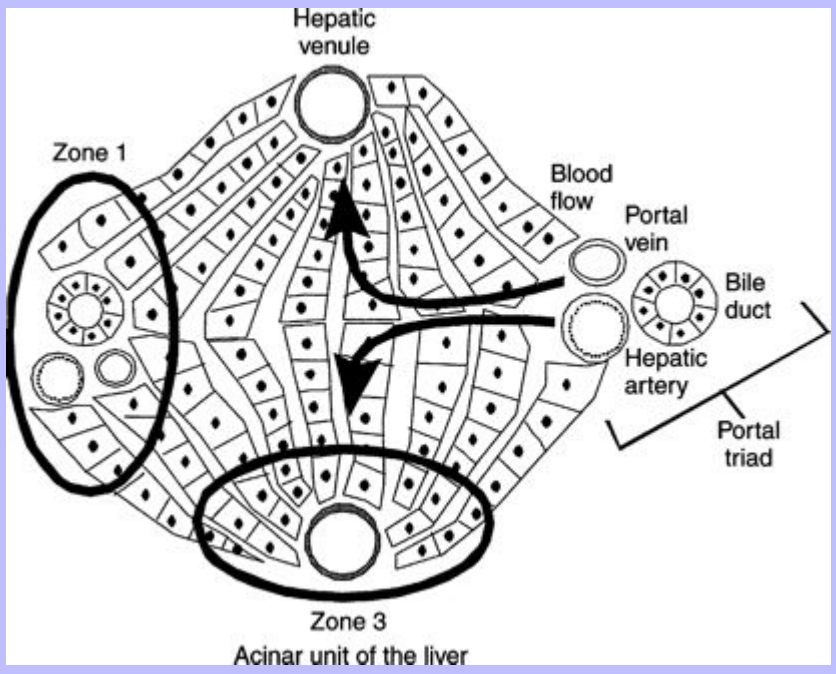
Margie A. Scherk

Sharon A. Center

230.1 INTRINSIC AND IDIOSYNCRATIC XENOBIOTIC HEPATOTOXICITY

Deriving 75% of its circulation directly from splanchnic venous drainage, the liver receives direct and concentrated delivery of xenobiotics (drugs and environmental chemicals) absorbed from the gut. Consequently, because of this central position in drug metabolism and disposition, the liver is a preferential target for adverse xenobiotic reactions. Many xenobiotics are capable of causing some degree of liver injury; these are broadly classified as intrinsic or idiosyncratic, although a combination of reactions also may occur.[1] Intrinsic hepatotoxicity is a result of the direct action of a xenobiotic or its metabolite on vital cell targets; a prototype of this form of injury is acetaminophen. Biochemical and morphologic features of intrinsic hepatotoxins reflect either extrinsic mechanisms or intracellular events and many damage zone 3 (Figure 230-1). The most common hepatic reaction with intrinsic drug toxicity is necrosis without an inflammatory infiltrate. Although drug-metabolizing enzymes detoxify many xenobiotics and toxins, they also enhance the toxicity of some.

Figure 230-1 Microscopic liver architecture: acinar unit of the liver.



Unlike intrinsic toxicity, idiosyncratic injury is thought to commonly involve immune-mediated mechanisms that either invoke specific cell surface death receptors, signaling apoptosis or necrosis, or involve hapten and

neoepitope expression on the hepatocyte surface. Idiosyncratic hepatotoxicity can exhibit either a regional or mixed zonal pattern.

Because the liver has an enormous regenerative capacity, replacement of lost hepatocytes may mask detection of drug-induced injury. The outcome of intrinsic and idiosyncratic xenobiotic hepatotoxicity varies widely, ranging from cell survival to apoptosis or complete cytolytic necrosis. Nutritional status affects xenobiotic toxicity, with obesity favoring the accumulation of lipid-soluble toxic metabolites and anorexia or protein: calorie restriction resulting in reduced hepatic glutathione (GSH) concentrations that can increase the hepatotoxicity of certain agents. 1465

230.1.1 Xenobiotic Hepatotoxicity: Morphologic Lesions

Drug-induced liver injury can mimic all forms of spontaneous liver disease. Lesions that may be linked with xenobiotic hepatotoxicity, include hepatocellular necrosis, toxic hepatitis, steatosis, and cholestasis (canalicular stasis with periportal inflammation). A summary of xenobiotics-related hepatotoxic reactions is provided in Table 230-1. The most common effects are described below.

Hepatocellular necrosis associated with xenobiotic toxicity may be zonal (often zone 3) or panlobular. Clinically, illnesses may range from an asymptomatic increase in transaminase activity to jaundice and overt hepatic failure. Intrinsic hepatotoxins can produce vague gastrointestinal (GI) signs, abdominal discomfort within a few hours to days of exposure (e.g., diazepam (cats) and carprofen (dogs)). In some cases, clinical signs resolve within days of xenobiotic withdrawal, however, in others, overt liver failure develops within 1 week and is associated with sequentially increasing liver enzymes, jaundice, coagulopathies, evidence of proximal renal tubular injury (i.e., granular casts, renal glucosuria), acute renal failure, and neurobehavioral changes indicative of hepatic encephalopathy.

Toxic hepatitis is characterized by diffuse or multifocal hepatic necrosis and degeneration with or without canalicular cholestasis. Hepatic acinar structure is maintained, but areas of necrosis and degeneration are surrounded by viable hepatocytes (+/− degenerative features) and an inflammatory infiltrate (mononuclear, macrophages, or eosinophils). Illness can range in spectrum from asymptomatic increases in transaminases to signs of overt liver failure and jaundice.

Steatosis (cytosolic fatty vacuolation) reflects the abnormal accumulation of triglycerides in hepatocytes in either a macrovesicular or microvesicular pattern. With the exception of hepatic lipidosis in cats, mild to moderate fatty vacuolation of hepatocytes may accompany “toxic” hepatitis. Microvesicular steatosis is thought to reflect severe metabolic disruptions associated with abnormal mitochondrial function. When diffuse, this lesion often accompanies inflammation and hepatocellular necrosis.

Cholestasis induced by xenobiotic toxicity results from the disruption of bile production or flow and may present as a periportal inflammatory lesion causing hepatocanalicular cholestasis or a less obtrusive, canalicular dysfunction without inflammation or necrosis. The major evidence for this form of injury involves sequential increase in alkaline phosphatase (ALP) and GGT activity, and the development of hyperbilirubinemia. 1465 1466

Table • 230-1 Histologic Patterns of Xenobiotic Associated Hepatic Injury

PATTERN OF INJURY	MECHANISMS	PROTOTYPE XENOBIOTICS
Zonal necrosis	Xenobiotic adducts, free radicals, neoantigens	Acetaminophen, halothane
Toxic hepatitis	Hapten formation →neoantigen	Phenytoin, sulfonamide, isoniazid
Microvesicular steatosis	Impaired hepatic B-oxidation of fatty acids	Tetracycline, valporic acid, tamoxifen
Macrovesicular steatosis	Increased triglyceride synthesis, reduced egress	Anabolic steroids in inappetent cats
Phospholipidosis	Formation of lysosomal inclusions	Amiodarone
Canalicular Cholestasis	Decreased membrane fluidity, Na/K ATPase	Anabolic hormones, estrogens, androgens
Hepatic cholestasis	Inflammation, Damage to bile canaliculi	Chlorpromazine
Veno-occlusive disease	Occlusion of terminal hepatic venules	Azathioprine, 6-thioguanine
Peliosis hepatica	Damage to sinusoidal membranes	Anabolic androgenic hormones
Hepatic xeoplasia	Unclarified	Sex hormones
Mixed inflammatory patterns	Immune-mediated to product/adduct	Many drugs

230.1.1.1

Box • 230-1 Known Hepatotoxins

Azathioprine

Carprofen (dogs)

Clonazepam (cats)

Diazepam (cats)

Danazol (dogs)

Acetaminophen (dogs and cats)

Methimazole (cats)

Methoxyflurane (dogs)

Mitotane (dogs)

Oxibendazole (dogs)

Phenytoin (dogs)

Primidone (dogs)

Phenobarbital (dogs)

Stanozolol (cats)

Thiacetarsemide (dogs)

230.1.1.1.1 Commonly Reported Toxins

Amanita mushrooms

Aflatoxins/mycotoxins

Blue-green algae: cyanobacteria

Cycad (Sago palm nuts)

Chlorinated compounds

Dimethylnitrosamine

Dinitrophenol

Heavy metals (Pb, Zn, Mn, Ar, Fe, Cu)

Phenols (especially cats)

230.1.1.1.2 Endotoxins and Enterotoxins

Enteric organisms: *Clostridium perfringens*, *C. difficile*

Food poisoning: Staphylococcal, *Escherichia coli*, *Salmonella*, *Bacillus cereus*

230.1.2 Specific Hepatic Xenobiotic Toxicities

A list of known hepatoxins follows.

230.1.2.1 Antimicrobial Hepatotoxicity

Antimicrobial hepatotoxicity, Table 230-2, has been widely recognized in humans and less commonly reported in veterinary patients. Trimethoprim-sulfa reactions are the best recognized example in dogs. Tetracycline therapy can result in fulminant hepatic failure in both dogs and cats as well as hepatic lipidosis.

230.1.2.2 Anticonvulsants: Phenobarbital, Phenytoin, and Primidone

Phenobarbital hepatotoxicity is the best-characterized "idiosyncratic" reaction in the dog, and has been well studied in this species as an enzyme inducer. It is clinically recognized as a hepatotoxin in some epileptic dogs. Clinical signs may include sedation and ataxia due to impaired drug metabolism. Anorexia, ascites, jaundice, and coagulopathy develop when liver damage is severe. A direct dose-related hepatotoxicity is not consistent. Clinical signs can develop within several months or years of phenobarbital initiation. Most dogs have been treated for over 1 year before showing clinical signs. Despite substantial hepatic injury, dogs may appear to be physically healthy despite abnormal serum chemistry values. Remission of clinicopathologic features and improvement in hepatic injury may occur after drug discontinuation. Dose reduction may produce improvement, but this is not well documented. Necropsies in dogs succumbing to hepatic insufficiency usually confirm chronic liver injury or cirrhosis. Lesions are identical to those described in dogs with primidone hepatotoxicity as 25% of primidone is metabolized to phenobarbital, and cannot be differentiated from dogs with other forms of chronic parenchymal liver injury.[2] Combination therapy of phenobarbitol and primidone increase the risk of hepatotoxicity.

1466
1467

Table • 230-2 Antimicrobial Hepatotoxicity

ANTIBIOTICS	TYPE OF LIVER INJURY
Penicillins	
Amoxicillin	Hepatocellular
Ampicillin	Hepatocellular
Amoxicillin/clavulanic acid	Cholestatic*, mixed vanishing bile duct lesions, granulomatous
Carbenicillin	Mixed
Nafcillin	Cholestatic
Oxacillin	Cholestatic, granulomatous
Penicillin G, V	Hepatocellular
Timentin	Cholestatic
Cephalosporins	Mixed, cholestatic
Ceftriaxone	Biliary sludge/stones
Cephalexin	Granulomatous
Tetracyclines	Hepatic lipidosis*,* fulminant hepatic failure* (dogs, cats)
Macrolides	
Erythromycin	Cholestatic*, vanishing bile duct lesions
Azithromycin	Cholestatic
Clarithromycin	Cholestatic
Clindamycin	Acute hepatocellular injury
Sulfonamides	Cholestatic*, hepatocellular*, mixed, granulomatous, fulminant liver failure*
Trimethoprim-Sulfa	Cholestatic, hepatocellular, mixed, granulomatous, fulminant liver failure* (dogs)
Antifungal	
Ketoconazole	Hepatocellular*, mixed, fulminant liver failure
Fluconazole	Hepatocellular*, cholestatic
Itraconazole	Hepatocellular
Flucytosine	Hepatocellular
Griseofulvin	Hepatocellular, cholestasis (cats)*
Antiparasitic Agents	
Albendazole	Hepatocellular, mixed
Mebendazole	Hepatocellular*, mixed, fulminant hepatic failure*
Thiabendazole	Mixed*, vanishing bile duct syndrome with diethylcarbamazine, necrosis (dogs)
Oxibendazole	

From Brown SJ, Desmond PV, Hepatotoxicity of antimicrobial agents. *Seminar Liver Dis* 2002; 22:157-67

* Antimicrobial drug hepatotoxicity reported in humans but pertinent to veterinary patients.

Phenytoin, a potent enzyme inducer can cause hepatitis, jaundice, and death in dogs when used as an anticonvulsant, especially when administered in combination with either phenobarbital or primidone. A dose-independent chronic hepatitis may progress to cirrhosis and appears to be reversible if the drug is discontinued promptly after initial signs of illness. Rarely, acute hepatotoxicosis has been observed.

230.1.2.3 Diazepam

Diazepam-associated hepatotoxicity in cats appears to be an idiosyncratic reaction. It causes severe panlobular hepatocellular necrosis sparing the biliary epithelium. Affected cats received these agents for behavior modification (e.g. inappropriate urination). Hepatotoxicity is recognized within the first week (several days) of oral drug administration. Initial clinical signs include inappetence, vomiting, and severe lethargy associated with transaminases progressively rising levels. After several days, ALP GGT and

bilirubin levels progressively increase activities progressively and cats become overtly jaundiced. Clinicopathologic abnormalities may progress to reflect fulminant hepatic failure, including hypoglycemia, profound coagulopathies, high creatinine kinase activity (muscle and myocardial necrosis), granular casts, and acute renal failure. Cats who have survived fulminant hepatic failure have received blood transfusions, plasma, vitamin K_1, water-soluble vitamins, parenteral feeding, and aggressive fluid and electrolyte support. Administration of N-acetylcysteine (NAC) is recommended. Surviving animals have persistently high ALP and GGT activity for several weeks to months after recovery due to regeneration, and hyperplastic biliary epithelium. Similar toxicity has been observed in cats receiving oral clonazepam.

230.1.2.4 Oxibendazole and Mebendazole

Administration of a combination heartworm-hookworm preventative containing diethylcarbamazine and oxibendazole has been associated with lethal hepatotoxicity in dogs. Clinical signs developed 2 to 4 weeks after the initiation of treatment and included lethargy, anorexia, vomiting, diarrhea, polydipsia, polyuria, and weight loss. Biochemical profiles reflected hepatocellular injury and cholestasis.

230.1.2.5 Methimazole

Methimazole used to treat hyperthyroid cats may be associated with cholestatic hepatotoxicity. This usually occurs within the first month of therapy and is indicated by increased liver enzyme activity (transaminases, ALP) and jaundice. Liver injury appears to be reversible with early drug discontinuation. Because metabolism of toxic intermediates involves GSH, it is postulated that patients with subnormal hepatic GSH concentrations may beat an increased risk for hepatotoxicity.[3] Although not yet studied in the cat, hyperthyroidism in other species reduces hepatic GSH concentrations, possibly from to increased oxidative stress associated with the enhanced metabolic rate. Because catabolism and protein deficiency states can enhance hepatic GSH depletion, certain symptomatic hyperthyroid cats may be at increased risk for methimazole toxicity. Cats with pre-existent liver disease associated with GSH depletion (e.g., cholangitis, cholangiohepatitis) may also be at increased risk.[4] This coincides with the observation that cats with cholangitis/cholangiohepatitis may become increasingly symptomatic when hyperthyroid.

230.1.2.6 Nonsteroidal Anti-inflammatory Drugs

Because NSAIDs are being used more often in the treatment of inflammatory and painful conditions, it is important to be observant for not only gastric and renal effects of prostaglandin inhibition but also for potential hepatotoxic effects. The mechanism by which hepatic toxicity occurs with most NSAIDs is not known, but it is not related to prostaglandin inhibition. NSAID-associated hepatopathy is believed to be idiosyncratic. Thus it is reasonable to obtain baseline biochemistry values (alanine aminotransferase [ALT], alkaline phosphatase [ALP], blood urea nitrogen [BUN], creatinine, total protein, packed cell volume [PCV]) because these agents can be associated not only with idiosyncratic hepatotoxicity but also with dose-dependent GI bleeding and exacerbation of renal insufficiency.

Nearly all nonsteroidal anti-inflammatory drugs (NSAIDs) can cause an asymptomatic increase in transaminase activity in humans. Usually enzyme activity normalizes rapidly upon treatment of cessation. Virtually all NSAIDs can cause some form of liver injury. There is no clear correlation between chemical class of NSAID and risk of hepatotoxicity. The histologic type of injury varies within and between classes. Although hepatocellular injury is most common, cholestatic injury, mixed injury, steatosis, and granulomatous reactions also are described in humans. Since many toxic metabolites are normally

detoxified by GSH, some metabolites may become more injurious when hepatic GSH stores are depleted (e.g. in patients with chronic necroinflammatory and cholestatic liver disease).[5]

Two NSAIDs are directly hepatotoxic: aspirin and phenylbutazone. In humans, the effects of aspirin are predominantly dose-dependent, anicteric, rarely fatal, and are reversible when treatment is discontinued. Carprofen (see below), a propionic acid derivative is recognized to cause severe and sometimes lethal idiopathic hepatotoxicity in dogs. Reye's syndrome, an unusual adverse response to aspirin, occurs in children with viral infections and results from mitochondrial toxicity.

230.1.2.6.1 Acetaminophen

Acetaminophen is widely recognized to provoke hepatotoxicity through induction of the p450 enzyme and impairment of hepatic GSH concentrations. Treatment with thiol donors to restore circulating and liver GSH status, or that directly conjugate toxic adducts can attenuate acetaminophen hepatotoxicity. Both NAC and S-adenosyl-L-methionine (SAMe) have been proven to do this. Dogs have an apparent predisposition to acetaminophen-induced liver damage due to their intrinsically low hepatic GSH concentrations relative to that of other species.[5] Cats have higher hepatic GSH concentrations and do not succumb to hepatotoxicity. Rather, they develop oxidative damage to their rbcs (red blood cells) (Heinz body anemia, methenoglobinemia) because of labile sulfhydry bonds in their hemoglobin, and endothelial toxicity.

230.1.2.6.2 Carprofen

Carprofen is a lipophilic, propionic acid class NSAID useful for the amelioration of pain associated with osteoarthritis. It can provoke idiosyncratic cytotoxic hepatotoxicity in some dogs.[6] Severity of cytotoxic injury varies among dogs and appears unrelated to dose or duration of treatment. Most dogs have received treatment for at least 2 weeks before showing vague signs of toxicity: anorexia, vomiting, lethargy, and polyuria/polydipsia (PU/PD). Some dogs with occult hepatic injury lack clinical illness. Common clinicopathologic abnormalities include modest to markedly increased transaminases (exceeding increases in ALP). Renal toxicity (granular casts, glucosuria in the absence of hyperglycemia, and proteinuria) may also occur. Some dogs succumb to fulminant hepatic failure, although most recover after drug withdrawal and 1–2 weeks of hospitalized supportive care. It is unclear whether chronic inflammatory liver disease precedes or follows acute toxicity.

230.1.2.7 Natural or Herbal Remedies

Awareness of the potential hepatotoxicity of herbal preparations and other botanicals Many herbal remedies are believed to be harmless and are commonly used without adequate medical supervision. The true frequency with which botanicals cause hepatic damage is unclear but it is important to remain alert for a causal relationship when liver injury is identified. A list of hepatotoxic associations with different herbal remedies is provided in Table 230-3.[5] 1467 1468

Table • 230-3 Herbal Remedies Associated with Hepatotoxicity

AGENT/PRODUCT NAME	TOXIC INGREDIENT	EVIDENCE/TYPE HEPATOBILIARY INJURY
African remedy	*Atractylis gummifera*	Diffuse hepatic necrosis; acute onset within hours
(Mediterranean/African regions)	*Callilepsis laureola*	Mitochondrial toxins
Bajiaolian	Podophyllotoxin	Abnormal liver tests
Chaparral leaf	*Larrea tridentata*, nordihydroguaiaretic acid	Fulminant hepatic necrosis, zone 3 necrosis, chronic hepatitis, cholestasis, cirrhosis
Chinese Herbal Medicine	Glycyrrhizin	Vanishing bile duct syndrome
Chinese Herbal Tea	*T u san-chi' I* (*Compositae*)	Veno-occlusive disease
Comfrey (*Symphytum officinale*) (gordolobo yerba, tea, maté)	Pyrrolizidine alkaloid	Veno-occlusive disease
Dai-saiko-to (differs from Sho-saiko-to in proportion of components)		Acute and chronic hepatitis
European remedy	*Chelidonium majus*, other *Neoclerodane diterpenes*,	Hepatitis, fibrosis, eosinophilic inflammation Zone 3 hepatitis, necrosis,
Germander	*Teucrium chamaedrys*	fibrosis, cirrhosistoxicity enhanced by p450 cytochrome induction and glutathione (GSH) depletion
Herbal teas comfrey, *Heliotroprium*, *Senecio*, *Crotalaria*, *Symphytum*, *T'u-san-*[*Compositae*]	Pyrrolizidine alkaloid	Veno-occlusive disease
Jin Bu Huan	*Lycopodium serratum*	Acute/chronic hepatitis, fibrosis, steatosis
Kombucha "mushroom"	Yeast-bacterial aggregate	Abnormal liver tests
Ma-huang	Ephedrine many other ingredients	Acute hepatitis
Margosa oil	*Azadirachta indica*	Hepatic lipidosis associated with diffuse mitochondrial failure
Mediterranean traditional remedy	*Teucrium polium*	Zone 3 necrosis, fibrosis, acute liver failure
Mixed preparations: mistletoe, valerian, skullcap	Unknown	Hepatic injury, laboratory abnormalities
Natural laxatives	Senna, podophyllin, aloin	Abnormal liver tests
Oil of cloves	Eugenol	Direct-dose hepatotoxin
Pennyroyal oil (home-made tea)	Labitae (mint)	Zone 3 necrosis, liver test abnormalities, pulegone depletes glutathione
	Mentha pulegium; pulegone → menthofuran pulegone	
Prostata	Saw palmetto *Serenoa serrulata, Pygeum africanum, other ingredients*	Hepatitis, fibrosis, cholestasis
Sassafras	*Sassafras albidum*	Hepatic carcinogen (animals)
Sho-saiko-to (TJ-9)	*Scutellaria*, others	Zonal, bridging necrosis, fibrosis, microvesicular steatosis, cholestasis
Chinese name: Xiano-Chai-Hu-Tang	Many components	Acute hepatitis, focal steatosis
	Venencapsan (horse chestnut leaf, sweet clover, celandine, milk thistle, dandelion root, milfoil)	
Zulu remedy	*Callilepsis laureola*	Hepatic necrosis

230.1.3 General Treatment Recommendations

If acute ingestion of a hepatotoxin within the preceding 8 hours, prompt is suspected emesis, gastric lavage, high enema cleansing, and administration of activated charcoal (orally and by enema) is recommended. Animals with reduced consciousness or active enteric bleeding should not be made to vomit or have vigorous enema manipulations performed for fear of causing aspiration pneumonia or exacerbating hemorrhage. Activated charcoal may importantly reduce enterohepatic circulation of certain toxins and should be administered. Antioxidant supplementation is warranted. Although not clearly a direct antidote for every form of xenobiotic hepatotoxicity, administration of NAC is safe, and may guard against hepatocellular thiol depletion. It is important that NAC be injected as a slow bolus rather than as a constant rate infusion. Using a nonpyrogenic 0.2 μm filter, give 140 mg/kg; subsequently give 70 mg/kg up to 4–6 times daily slow IV. Once oral medications can safely be administered, initiate same 20 mg/kg PO. Same is best administered on an empty stomach to ensure availability of this pivotal metabolic substrate. Supplementation with alpha-tocophetol (vitamin E, 101 u/kg orally per day) is also suggested. In fulminant hepatic failure, provision of clotting factors by administration of fresh frozen plasma is advised (2 to 5 mL/kg intravenously), along with vitamin K_1 (0.5 to 1.5 mg/kg subcutaneously, every at 12-hour intervals for three doses). For certain xenobiotics, particularly early after acetaminophen ingestion, cimetidine is administered with the intent of impairing cytochrome p450 activity responsible for generation of toxic adducts. Fluid therapy is provided to ensure adequate hydration, not only for normal circulatory support, but also for maximal biliary and renal excretion of toxic adducts. Fluids should be supplemented with B complex vitamins (1 to 2 mL/liter of fluid), along with KCl (judiciously using conventional sliding scale doses), phosphate, and magnesium according to needs. Glucose supplementation is important for patients in fulminant hepatic failure or demonstrating proximal renal tubule injury with glucosuria when hypoglycemia is recognized. For toxins that are highly protein bound and difficult to eliminate, administration of medications with competitive protein binding may exacerbate toxicity. For animals with declining oncotic pressure, administration of synthetic colloids (hetastarch, Dextran-70) is advised. Because colloids may result in platelet-associated bleeding tendencies, fresh frozen plasma is preferred in animals in fulminant hepatic failure prior to colloid administration.

1468
1469

Clinical use of Milk Thistle (silibinin) remains controversial, except for intervention of amanitin-associated mushroom toxicity.[5] The active constituents, flavonolignans including silibinin, isosilibinin, silidianin, and silicristin, are collectively known as *silymarin*; silibinin is the principle active ingredient. This herbal product is thought to be a hepatoprotective, antioxidive, antiinflammatory, antifibrotic, and to promote hepatic regeneration. No evidence indicates that silymarin poses a toxic effect, although standardization of products and purity is unregulated. Doses of 20 to 50 mg/kg of 60% to 80% potency silymarin extract may be appropriate for dogs; studies of *Amanita phalloides* hepatotoxicosis used 50 to 150 mg/kg successfully.[5]

Nutritional support is critical for animals recovering from acute xenobiotic toxicity. Protein restriction should not be imposed unless signs of hepatic encephalopathy are recognized; undue restriction may impair a positive nitrogen balance needed for tissue regeneration.

Sequential evaluation of liver enzymes (transaminases in particular), total bilirubin (where elevated), and serum bile acids (SBA) (in those with normal bilirubin) can be used to monitor resolution of hepatocellular toxicity and improving liver functions. For lesions associated with reactive biliary epithelial hyperplasia, the serum ALP and GGT activities may increase for days after clinical improvement is firmly established.

Discontinuation of the suspected hepatotoxin is the most important interventional treatment for chronic xenobiotic hepatotoxicity. Intervention with glucocorticoids or other immunomodulating medications should

only be based on liver biopsy findings. Common involvement of *oxidative stress* argues for intervention with antioxidants, especially thiol donors (SAMe), and vitamin E until clinicopathologic findings indicate recovery. Ursodeoxychol acid is specifically indicated when high bile acid concentrations are a part of the disease process, but it has limited value in acute xenobiotic toxicity. If cholestasis is a component of chronic disease, accumulation of membranocytolytic hydrophobic bile acids justifies its use.[3]

230.2 METALS AND LIVER DISEASE

Because the liver is the first organ perfused by portal blood containing absorbed minerals, it can serve as a "sink" or "reservoir" for excessive quantities of absorbed materials or toxic metals. Copper and iron play a critical role in formation of reactive oxygen species (ROS); selenium and zinc contribute to ROS detoxification. Excess copper is primarily eliminated through the biliary system, thereafter undergoing an enterohepatic circulation. The transition metals copper and iron have been proven to accumulate in the liver tissue of dogs and cats with necroinflammatory liver disorders where they may enhance hepatic vulnerability to oxidant injury.[8]

230.2.1 Copper

Because copper is a transition metal, it has both pro-and antioxidant effects. Pathologic hepatocellular copper overload has been well described in Bedlington terriers as a genetic defect and has been observed randomly in other pure and mixed breed dogs and in a few cats. Serum ALT activity has been shown to correlate with mitochondrial copper concentrations, hepatocellular oxidant damage, and cytolysis in patients with inherited copper storage hepatopathy. The familial tendency for hepatic copper accumulation described in the West Highland white terrier does not consistently lead to liver injury. Copper retention is more commonly observed as a complicating feature of chronic cholestatic liver disease.

230.2.2 Iron

In approximately 80% of dogs with chronic necroinflammatory liver disease, tissue iron concentrations exceed the normal range.[9] Recent work suggests that although this iron appears morphologically isolated in hepatic Kupffer cells, other macrophages or lipogranulomatous inflammatory foci in liver tissue, it remains biologically active and may contribute to ROS formation and hepatic fibrosis.[7,9]

It is clear that iron is a profibrogenic factor based on extensive study of humans with hemochromatosis, a genetic defect resulting in hepatocyte iron loading. A central role in liver fibrogenesis associated with iron overload is the Kupffer cell, which in turn, activates nearby stellate cells, directly mediating collagen gene activation.

Therapeutic intervention in iron-related liver injury has been studied. High hepatic iron concentrations are associated with subnormal concentrations of vitamin E and a reduced GSH/GSSG balance in liver tissue. Hepatocytes depleted of GSH are more susceptible to iron-induced lipid peroxidation. In hemochromatosis, phlebotomy is the treatment of choice along with administration of antioxidant and hepatoprotective agents. Both vitamin E and silibinin attenuate iron-associated oxidative liver injury in this disorder.[10,11] One of the authors has rarely diagnosed apparent hemochromatosis-like hepatic disease in dogs and cats. These have been managed with phlebotomy (i.e., biweekly removal of no greater than 15% of blood volume), repeated based on circulating ferritin concentrations and serum iron indices (as well as chronic supplementation with antioxidants).

230.3 METABOLIC DISORDERS

230.3.1 Amyloidosis

Amyloidosis involving the liver is uncommon but may occur as a component of systemic amyloidosis, a syndrome resulting from multiorgan extracellular amyloid deposition. Amyloid is made up of a number of different amyloidogenic proteins reflecting a diversity of disease processes. All amyloid proteins share a pleated structure, resulting in a characteristic green birefringence when stained with Congo red and viewed with polarized light. In systemic amyloidosis of dogs and cats, the precursor protein is typically amyloid A (AA), an amino terminal fragment of the acute-phase protein, serum amyloid A (SAA). This protein may occur secondary to sustained acute-phase reactions associated with chronic inflammatory, infectious, or neoplastic diseases or as a familial trait as it does in man.

1469
1470

In systemic amyloidosis, the clinical signs vary corresponding to the pattern and extent of tissue involvement. In familial AA amyloidosis in Chinese Shar Pei dogs and in Abyssinian cats, the most common presentation involves renal involvement. Systemic familial amyloidosis involving the liver has been described in a small number of dogs, and in Siamese, Oriental shorthair, Devon Rex, Burmese, and DSH cats.[12–15] Investigation of amyloid protein in Siamese and Abyssinian cats suggests a unique isotype in the Siamese. Diffuse hepatic involvement predisposes to spontaneous hepatic rupture, owing to increased organ fragility and the presence of a coexistent coagulopathy (inhibition or deficiency of factors, binding of ionized calcium, or deficiency of vitamin K). Cats present suddenly dead or hypothermic with acute signs of hemorrhage from ruptured liver lobes (anemia, hemorrhagic abdominal effusion). A regenerative anemia, presence of Howell Jolly bodies due to splenic dysfunction from amyloid deposition, a “stress” leukocytosis, and poikilocytes are observed. Thrombocytopenia and abnormally prolonged clotting times are common in cats with hepatic rupture; some cats respond to vitamin K_1. Increased ALT is common, but some cases lack biochemical features indicating hepatic involvement. A familial cluster of cases is common. Hepatic ultrasonography initially may reveal a diffusely hypoechoic liver.

Definitive diagnosis requires tissue biopsy and histopathologic demonstration of amyloid. Cytologic evaluation of an hepatic aspirate may suggest (but not definitively confirm) the presence of amyloid, based on the identification of pink amorphous material adjacent to hepatocytes (with a modified Wright's-Giemsa stain). Caution is warranted before collecting liver samples because either aspiration or biopsy may initiate uncontrollable hemorrhage. On gross inspection, affected liver or spleen appear pale and enlarged, with rounded edges. The intestines may be dilated reflecting dysmotility secondary to amyloid deposition.

Colchicine is used in the treatment of familial Mediterranean Fever in man (similar to the periodic fever syndrome in Shar Pei dogs). It attenuates inflammation by interfering with release of inflammatory mediators, neutrophil participation, and deposition of amyloid fibrils. Clinical signs (several dogs) and histologic severity of hepatic amyloid deposition (as reported in one dog) have been blunted in Shar Pei dogs treated with colchicine (0.03 mg/kg orally per day). No experience exists with colchicine in cats with systemic amyloidosis and liver involvement. Colchicine has been used in a few cats with hepatic fibrosis (0.03 mg/kg orally, once a day to every other day). Acute treatment of liver hemorrhage requires generous provision of fresh whole blood and plasma transfusions. A grave prognosis is warranted for cats with hepatic amyloid; survivors eventually succumb to renal failure or acute hypovolemic shock from liver lobe fracture.

230.3.2 Feline Lipoprotein Lipase Deficiency

Lipoprotein lipase (LPL) regulates the dispersal of fatty acids to muscle and adipose. Deficiency disturbs fat metabolism leading to hypertriglyceridemia, hyperchylomicronemia, and systemic sequela of these aberrations. Several kindreds of cats with familial LPL deficiency have been studied; this defect is an autosomal recessive trait.[16,17] Compared with normal cats, affected cats have more than tenfold increase in circulating triglycerides yet normal total cholesterol. Kittens do not exhibit clinical signs other than fasting lipemia; they grow normally and show clinical signs at 8 to 9 months of age, including fasting hyperlipemia, lipemia retinalis, cutaneous xanthogranulomas (lipogranulomas), and peripheral neuropathies due to the compression of lipogranulomas in areas of minor trauma. Treatment involves feeding a diet restricted in fats and triglycerides. Peripheral neuropathies may resolve or improve after several months on a fat-restricted diet.

230.3.3 Canine Hyperlipidemia

Abnormalities in canine lipid metabolism have received limited attention. Affected breeds include Miniature Schnauzers, Shetland Sheepdogs, Briards, Beagles, certain terrier breeds (especially Scottish terriers, West Highland white terriers, Cairn terriers), and some mixed breed dogs. Hyperlipidemia in the dog predisposes to development of a diffuse vacuolar hepatopathy or biliary mucocele. Vacuolar hepatopathy may be associated with excess hepatocyte glycogen and/or lipid inclusions. Biliary mucocele formation may reflect the influence of hypercholesterolemia on biliary cholesterol concentrations and appears to be augmented by age-related cystic hyperplasia and possible dysmotility of the gallbladder wall.

In the developmental stage, biliary mucoceles are asymptomatic and are serendipitously discovered during abdominal ultrasound performed for unrelated reasons. Dogs with large biliary mucoceles may present for associated necrotizing cholecystitis or they may be found ultrasound investigation for high liver enzyme activity (especially ALP). Many cases have a coexistent diffuse vacuolar hepatopathy causing a diffuse or multifocal hepatic parenchymal hyperechogenicity, hypoechoic nodules, nongravitational gallbladder “sludge,” and a thickened, bi-or trilaminar appearance of the gallbladder wall. The appearance of a “kiwi” fruit echoimage within the gallbladder lumen is diagnostic for a firm, well-established mucocele. These must be surgically removed, the urgency depending on clinical evidence of necrotizing cholecystitis (hyperbilirubinemia, high liver enzymes, cranial abdominal pain, leukocytosis). Dogs with severe hypothyroidism can also develop pathologically significant hypercholesterolemia, hepatic vacuolation, high liver enzyme activity associated with abnormally increased SBA concentrations, hyperbilirubinemia, and biliary mucoceles. Initiating thyroxin therapy for 1 to 2 weeks before elective surgical removal of a biliary mucocele is advised in these dogs if clinical signs of the mucocele are minimal. Although liver lesions resolve with institution of thyroxine, mucoceles usually require surgical removal. At surgery, the gallbladder should be excised because mucoceles have been observed to reform. Chronic life-long treatment with a fat-restricted diet (in hyperlipidemic patients) and chronic administration of ursodeoxycholic acid (15 mg/kg orally per day) is recommended for dogs with biliary mucoceles, even after their removal.

230.3.4 Canine “Steroid or Glycogen” Vacuolar Hepatopathy

The hepatic response to glucocorticoids varies remarkably among species. In the dog, rapid change in hepatic morphology and induction of liver enzymes is well recognized. High dose glucocorticoid administration usually causes significantly increased ALP and ALT activity within 2 to 3 days if given by injection and within 1 to 2 weeks if given orally.[18] Individual variation in response, different potencies of glucocorticoid

agents, and route of exposure (endogenous, parenteral, oral, cutaneous, ocular) influence changes in hepatic morphology, clinicopathologic features, and clinical signs. Typically, increased ALP and GGT activity develop in parallel as these enzymes undergo induction and subsequent release from sinusoidal and canalicular membranes. Initially, (during the first week of glucocorticoid exposure) a liver-ALP isoenzyme predominates. This is rapidly replaced (within 1 week) with a glucocorticoid-ALP isoenzyme.[19] Because most canine patients with increased ALP activity produce the glucocorticoid-ALP isoenzyme, clinical utility of isoenzyme fractionation is low.

1470
1471

In the seminal study of glucocorticoid hepatopathy in the dog (injectable prednisone daily for 14 days), hepatocellular glycogen gradually increased, achieving maximal values on the fifteenth day. Glycogen accumulated first in zone 1 but thereafter predominated in zone 3 resulting in typical *ballooning degeneration*. After discontinuation of glucocorticoids exposure, hepatocellular glycogen slowly diminished over a period of weeks. Ultrasonographic features of vacuolar hepatopathy include diffuse or multifocal parenchymal hyperechogenicity with variable appearance of hypoechoic nodules. Distinction from other chronic necroinflammatory or fibrosing liver disorders is impossible without tissue sampling.

A similar clinical scenario as that described for exogenous glucocorticoids occurs in dogs with adrenal hyperplasia syndromes, where high steroid sex hormone production or high cortisol production occurs. A confusing aspect of the vacuolar hepatopathy syndrome in dogs is its association with a variety of chronic health problems. These may reflect an aspect of patient stress response correlating with acute phase responses, resulting in enhanced production of endogenous corticosteroid or nonglucocorticoid steroid hormones (Box 230-2). If clinical scrutiny fails to disclose an underlying health problem or cortisol values consistent with classic hyperadrenocorticism in a dog with a prominent vacuolar hepatopathy associated with high ALP activity (often with modestly increased SBA concentrations), a sex hormone profile conducted before and after ACTH administration should be pursued. Samples may be sent to the University of Tennessee Endocrinology laboratory (UTCVM Clinical Endocrinology Laboratory Tests, Department of Comparative Medicine, Room A105, 2407 River Drive, Knoxville, TN 37996-4500; (865) 974-5638). Because severe vacuolar hepatopathy has been observed to progress to the severe lesions associated with the hepatocutaneous syndrome, one of the authors (SAC) has recently taken a more aggressive approach. Treatment is undertaken in patients with abnormally high sex steroids (single or multiple abnormalities involving androgen, progesterone, or estrogen hormones, without cortisol abnormalities) in the following circumstances: marked vacuolar remodeling with formation of reticulin-bound nodules, or clinical signs such as PU/PD, polyphagia, or evidence of compromised liver function (e.g., high bilirubin, high bile acids). Treatment with mitotane (op' DDD) has been successful; experience with trilostane is limited at present. L-deprenyl and melatonin treatment has been discouraging, and no experience exists with estrogen aromatase inhibitors in this syndrome.

230.3.5 Hepatic Lipidosis Syndrome in the Cat

Cats have a propensity for accumulating triglycerides (TG) in their hepatocytes. Systemically ill cats usually develop some degree of hepatocellular fatty vacuolation. The development of lipid vacuoles within hepatocytes is not directly noxious but rather reflects an underlying metabolic disorder. Hepatic TG accumulation is not problematic until the degree of vacuolation is morphologically severe. In a normal feline liver, the fat content comprises less than 5% of total organ weight. The liver of a cat with the HL syndrome may double or triple in weight from accumulated fat.

TGs accumulate when the rate of hepatic synthesis exceeds their dispersal. Hepatic TGs are produced from fatty acids derived from the systemic circulation (dietary lipids, adipose stores) and from *de novo* hepatic synthesis. Overnutrition, especially with carbohydrates, augments hepatic fat accumulation as a result of a

positive energy balance and an inhibitory metabolic influence on mitochondrial fat oxidation. Many cats developing HL are obese; unrestricted release of fatty acids from excessive adipose stores promotes HL, because up to one third of mobilized fat resides in the liver at any time. HL reflects the liver's inability to match fat dispersal with delivery from systemic sources. The balance of TG lipolysis and accumulation is modulated by blood glucose concentration, hormonal, neural, and pharmacologic mechanisms. The activity of hormone sensitive lipase (HSL, promoting lipolysis) and LPL (promoting fat uptake) directly regulate adipocyte fat metabolism. Norepinephrine, epinephrine, growth hormone, glucagon, corticosteroids, and thyroxin increase HSL activity, whereas insulin inhibits HSL. Because cats release catecholamines readily, 1471
stress may exacerbate HSL activity. This effect is augmented in the absence of insulin resulting in occult or 1472
overt HL in unregulated diabetic cats. The LPL activity promotes fat uptake into adipocytes in the well-fed individual. In starvation however, although LPL activity declines, HSL increases, this balance favoring hepatocellular fat accumulation. An obese individual undergoing self-imposed starvation (anorexia) consequently has increased risk for peripheral fat mobilization and hepatocellular uptake.

230.3.5.1 Box • 230-2 Differential Diagnoses for Canine Vacuolar Hepatopathy

230.3.5.1.1 Hyperadrenocorticism

Spontaneous disease

Pituitary or adrenal origin

Iatrogenic: glucocorticoids therapy:

PO, IM, SQ, topical: skin, eye, ear

The fate of fatty acids is diverse, including their consumption by beta-oxidation, conversion to phospholipids, use in formation of TG, cholesterol esters, to be packaged with apoproteins for dispersal as lipoproteins. An important mechanism of hepatic TG egress or dispersal is through formation of very low–density lipoproteins (VLDL). A variety of subcellular activities regulate VLDL dispersal from the hepatocyte, including lipid transport through subcellular compartments, combination with apoprotein, formation of secretory particle and vesicle, and expulsion into the perisinusoidal space. Impairment at any step or imbalance between essential lipoprotein components may compromise hepatic fat mobilization. The essential interaction of fatty acids and L-carnitine at the mitochondrial membrane for intraorganelle delivery and formation of activated fatty acid necessary for beta-oxidation may also play a role in development of the HL syndrome. The recently demonstrated deficiency of GSH in hepatocytes of these cats could represent dysfunction of the transsulfuration pathway. This, collectively considered with the common finding of B_{12} deficiency in the HL cat (especially those with substantial intestinal disease), supports defective availability or use of SAMe necessary for methylation reactions and de novo synthesis of L-carnitine. Studies of the influence of L-carnitine on fatty acid oxidation in the cat, and in modeled HL, support this association.[20,21]

Ultrastructural study of hepatocytes in HL cats documents reduced number of peroxisomes—organelles needed for oxidation of long chain fatty acids prior to mitochondrial delivery. This may further interfere with normal fat oxidation. Given the complexity of lipid metabolism, a multitude of factors likely predisposes any given cat to HL. Possible scenarios include an increased presentation of fat to the liver as a result of obesity, catabolism, chronic over-nutrition, enhanced *de novo* hepatic fatty acid synthesis, or impaired fatty acid oxidation or VLDL dispersal.

Cats of any age may be affected by HL; most commonly cats are between 4 to 15 years of age. Domestic shorthair cats are more commonly affected, which may reflect breed popularity. Initial clinical features

include inappetence and anorexia, weight loss, vomiting, lethargy, and weakness.[22] Physical findings include dehydration, variable icterus, an unkempt appearance, and palpable liver margins. Although fat may become depleted on the limbs and dorsal trunk, abdominal fat stores are spared.

Hematologic tests may disclose a nonregenerative anemia and a stress leukogram reflecting the disease causing anorexia. Poikilocytosis is common and may reflect altered red blood cell (RBC) membrane lipids, metabolism and oxidative stress altering cell membrane flexibility.

Biochemical changes reflect cholestasis, and to a lesser degree, altered hepatocellular membrane permeability and viability. Because the feline HL syndrome lacks necroinflammatory lesions, release of transaminase and ALP usually coexist. Rarely, a cat with HL will have high transaminases with only modest ALP activity. In HL without pancreatitis or inflammatory disease involving biliary structures, the GGT activity usually remains quiet. Hyperbilirubinemia and high SBA concentrations are common. Hypokalemia reflects inappetence and is significantly associated with failure to survive if uncorrected.[22] Hypochloremia may reflect vomiting. Hypophosphatemia reflects a multitude of effects on the intercompartmental homeostasis of phosphate, but most importantly it may occur as a consequence of a refeeding syndrome. A urinalysis reveals urobilinogen, bilirubin crystals, and bilirubin pigmenturia.

Ultrasound evaluation characteristically shows a hyperechoic hepatic parenchyma. Liver aspirates demonstrate hepatocellular lipid vacuolation. Aspiration cytology is good for identifying HL, hepatic lymphoma, and overt hepatic sepsis, but it is unreliable for detection of necroinflammatory disorders, especially cholangitis and cholangiohepatitis. Ultrasound examination is also important for inspection of disorders involving the pancreas, stomach, intestines, and biliary structures, which may have initiated the inappetence resulting in HL. Surgical or laparoscopic biopsy of the liver reveals a yellow-tan hepatic color and friable tissue. Histopathology of hepatic biopsies reveals profound vacuolation of hepatocytes. Presence of lipid within vacuoles is verified using Oil Red-O stain on frozen sections not paraffin embedded. It is important to look for other findings in the liver biopsy and in other sampled tissues for an underlying primary disease process.

Appropriate treatment requires client education regarding the likelihood of an underlying primary disease, the importance of critical supportive care, without which the condition has a poor prognosis and the infrequency of recurrence of lipidosis in survivors. Treatment may require weeks to months of assisted alimentation and metabolic support. Concurrent medical conditions must be managed. A recovery rate exceeding 85% can be achieved if a primary disease is identified and ameliorated or cured and the patient survives the initial 72 hours of critical supportive care.

The most important treatment is provision of a balanced feline diet delivering adequate energy intake (60 kcal/kg/day). Feeding is usually achieved using a feeding tube (esophagostomy tube being least invasive and easiest to manage with fewest complications). The number of feedings per day is determined based on the volume of food tolerated per meal. The diet is balanced to prevent protein-to-calorie malnutrition. Fat supplementation is contraindicated. Carbohydrate supplementation is ill advised (e.g., dextrose infusion) because of its inhibitory influence on fatty acid oxidation. Dietary protein restriction is reserved only for patients with irrefutable signs of hepatic encephalopathy. Placement of a large bore feeding tube is recommended after the patient is stable enough to tolerate anesthesia and bleeding tendencies have been circumvented by administration of vitamin K_1. Nasoesophagostomy tubes are used only short term to start patient nutritional support. Gastrostomy tubes may be placed at the time of surgery; esophagostomy tubes may be placed under a shorter anesthetic or at the time of surgery. The inappetent cat has increased risk for food aversion when confronted with forced oral alimentation. Tube placement is discussed in Chapter 92.

Vomiting must be controlled. Although this can be achieved medically (see Chapter 38), it may also be alleviated by reducing the feeding volume, increasing the number of meals per day, or by use of a *trickle feeding approach* with a syringe or fluid pump. Trickle feeding is accomplished by placing liquefied food into an empty fluid bag and administering it gravitationally or by pump assistance via an intravenous line attached to the large bore feeding tube or by use of a large syringe filled with food and syringe pump. Care must be taken to renew food and delivery tubing and syringe at 6-to 8-hour intervals to avoid bacterial contamination.

Fluid support is best provided intravenously with a nonlactate and nonglucose containing fluid. Lactate intolerance is suspected in the severe HL cat, and steady glucose infusion is thought to potentiate hepatic TG accumulation. Hydration is critical in any animal with severe hepatic insufficiency as is thought to exist in the HL cat. Dehydration impairs hepatic circulation, which can compromise normal detoxification processes. 1472
Azotemia increases diffusion of urea into the gut and subsequently, enteric ammonia production. Constipation 1473
may be augmented by dehydration and prolongs contact with and absorption of endotoxic enteric material. Cats demonstrating signs consistent with hepatic encephalopathy may benefit from lactulose administration. Aggressive attention to correction of hypokalemia is essential; this is accomplished using the customary sliding scale for fluid potassium supplementation.

Hypophosphatemia may precede initiation of nutritional support but more commonly reflects a refeeding phenomenon. Treatment of hypophosphatemia accomplished using potassium phosphate (delivered at 0.01 to 0.03 nmol/kg/hr) monitoring serum phosphate every 6 hours. Phosphate supplementation is discontinued when serum phosphorus greater than 2 mg/dL. Iatrogenic hyperkalemia is possible if the clinician fails to appropriately reduce KCl infusion rate given concurrently. Parenteral phosphate requirements resolve once alimentation is established.

Water-soluble vitamins should be added to intravenous fluids (1 to 2 mL vitamin B complex per liter). Cobalamin (vitamin B_{12}) deficiency should be suspected in HL cats with thickened intestines on palpation; treat by giving 1 mg B_{12} subcutaneously. Administration of B_{12} in a deficient cat with HL is critical because this imposes a significant metabolic deficit, limiting methylation reactions and endogenous SAMe production. Thiamine (vitamin B_1) deficiency also has been observed in cats presented for HL based on dramatic response to vitamin supplementation. Affected cats usually show severe neck ventroflexion; this also may occur with substantial hypo-phosphatemia, hypokalemia, hepatic encephalopathy, and a variety of disorders influencing neuromuscular or cervical vertebral function. Anaphylaxis may occur as a result of injected thiamine; oral rather than parenteral thiamine administration (50 to 100 mg per cat per day for 1 week in those demonstrating consistent clinical signs) may be preferable.

Cats with HL are often deficient in vitamin K as proven by the PIVKA (proteins induced in vitamin K absence or antagonism) or prothrombin time (PT) tests. Lack of dietary intake, altered intestinal bacterial flora as a consequence of antimicrobial treatment, impaired vitamin K epoxidase cycle associated with hepatic dysfunction are considered underlying causes. Subcutaneous treatment with vitamin K is recommended for three doses (0.5 to 1.5 mg/kg at 12-hour intervals). Further treatment may induce RBC oxidation and hemolysis. Correction of PIVKA clotting abnormalities typically occurs within this time. Vitamin K treatment must precede insertion of feeding appliances, jugular venipuncture, cystocentesis, hepatic aspiration, or hepatic biopsy.

Supplementation with 250 to 500 mg L-carnitine per day is warranted based on experimental data and on observed clinical response. L-carnitine is an essential cofactor of fatty acid oxidation. Although it may be derived from the diet, it also is normally synthesized endogenously from lysine and methionine. Methionine metabolism may be compromised in the HL cat, limiting transformation of methionine to SAMe. Because

SAMe generates GSH through the transsulfuration pathway and L-carnitine via methylation reactions, both depletion of GSH and L-carnitine may result. L-carnitine prevents accumulation of free fatty acids in the hepatocyte cytoplasm, as well as acetyl groups in the mitochondria where they inhibit beta-oxidation. It is surmised that the HL cat maintains a "relative" local hepatocellular carnitine deficiency regardless of adequate plasma or muscle carnitine concentrations. Taurine may also be supplemented (250 to 500 mg/day); this essential amino acid in the cat is necessary for normal bile acid conjugation. Owing to the compromised hepatic GSH shown in a small number of HL cats tested, antioxidant supplementation using vitamin E (10 IU/kg per day in food) and the thiol donor NAC intravenously during initial crisis (Heinz body hemolysis, recumbency) followed by SAMe there, (20 to 40 mg/kg through feeding tube is suggested. A higher dose SAMe than is normally used may be necessary because removal of the enteric coating for administration through the feeding appliance theoretically limits SAMe availability. Alternately administer 90 mg/day in an uncrushed tablet orally. Treatment of HL is summarized in Box 230-3.

230.3.5.2

Box • 230-3 Treatment of Hepatic Lipidosis in Cats

1. Supply 60 kcal/kg/day of balanced diet: protein restriction is contraindicated unless encephalopathy is present.
2. Correct dehydration and maintain hydration using non-lactate, non-glucose—containing fluids.
3. Supplement with vitamin k1 (0.5–1.0 mg/kg/day SC for 3 treatments at 12-hr intervals).
4. Place a large bore-feeding tube as soon as possible.
5. Correct hypokalemia.
6. Correct hypophosphatemia.
7. Supplement with 250–500 mg L-carnitine/day.
8. Supplement with water-soluble vitamins.
9. Supplement with 250–500 mg tawire/day.
10. Supplement with vitamin E (10 IU/kg/d PO), NAC for crisis intervention, SAMe (20–40 mg/kg/d via feeding tube).

230.4

STORAGE DISORDERS INVOLVING THE LIVER

230.4.1

Lysosomal Storage Disorders

Lysosomal storage disorders comprise a group of inherited juvenile or adult-onset disorders that show different clinical features depending on the particular metabolic aberration. Most of these are autosomal recessive traits and express as a consequence of line breeding.[24,25] Normal lysosomes degrade cellular and extracellular macromolecules, providing amino acids, fatty acids, nucleic acids, and carbohydrate residues for reuse. Primary lysosomes, derived from the Golgi apparatus, may fuse with other membrane-bound vesicles forming secondary lysosomes. Secondary lysosomes contain material derived from outside the cell through endocytosis or from within the cell by autophagy. Storage diseases are defined by the nature of the lysosomal hydrolase deficiency and resultant accumulating metabolic substrates or products. Disorders are suspected

based on clinical signs, including progressive neurologic dysfunction, ocular abnormalities, visceromegaly (including hepatomegaly), and skeletal abnormalities; signs may overlap clinically with nonlysosomal storage disorders.[24]

The different disorders that may be associated with hepatocellular or Kupffer cell storage product accumulation are described in Table 230-4. The mucopolysaccharidoses (MPSs) and disorders associated with interrupted catabolism of oligosaccharides can be crudely determined by specific urine tests (e.g., toluidine blue for detection of glycosaminoglycans reflecting MPS). Evaluation of peripheral leukocytes (looking for unusual lysosomal granules in granulocytes, lymphocytes, and monocytes) and staining blood smears with acid phosphatase (to confirm lysosomal vacuolation) can be helpful. Juvenile forms of certain storage diseases may be suspected from the appearance of vacuolated lymphocytes or monocytes in peripheral blood (e.g., mannosidosis, GM1-GM2-gangliosides, mucolipidoses). Ultrastructural examination of skin also can demonstrate lysosomal storage disorders, however it is not specific. Genetic testing for many disorders is available. Where this isn't possible, plasma, leukocyte, and tissue sampling with verification of storage products and enzyme deficiencies is necessary. For reliable assessments, samples from an age-and sex-matched peer group should be evaluated concurrently.

1473
1474

Treatment is limited for these disorders. Bone marrow transplantation and enzyme replacement studies have been conduced on canine MPS type I and VII, feline MPS type VI, canine fucosidosis, and feline α-mannosidosis. Although variable improvements have been documented, this is not a practical recommendation and without neutering permits perpetuation of the genetic defect. Bone marrow transplant failed to improve advanced ceroid-lipofuscinosis in English setters.

230.5 HEPATOBILIARY INFECTIONS

The central position of the liver between the enteric and systemic circulation makes it an important interventional mechanism guarding against infectious agents. Normally, enteric flora entering the portal venous circulation by enteric transmural migration are killed or extracted by the hepatic macrophages (Kupffer cells), migrating macrophages, with neutrophils, and some being eliminated in bile. Locally produced immunoglobulins, primarily IgA, cooperate in providing innate immune defense. A number of conditions are known to predispose to hepatobiliary infections (Box 230-4).[23] Ischemic and hypovolemic injury decrease hepatic perfusion and impair macrophage function. The interruption of normal choleresis as occurs in cholestasis of any cause may result in infections derived from normal enteric organisms as rapid elimination of bacteria becomes compromised.

Table • 230-4 Storage Disorders Involving the Liver

CLASS	STORED PRODUCT/DEFICIENT ENZYME	TISSUES IMPACTED	REPORTED IN
Sphingolipidoses	Sphingolipids	Nervous tissues, liver, macrophages, granulocytes	Dogs and cats
Glycoproteinosis	Sugars	Hepatocytes, renal and neural cells	Cats: Persians, DSH
Mannosidosis			Springer spaniels, other dogs
Fucosidosis			
Mucopolysaccharidoses (MPSs)	Glycosaminoglycans (GAGs) (sulfates of dermatan, heparan, keratan, & chondroitin)	Wide tissue involvement, growth deformities, may observe storage produce in: Hepatocytes, Kupffer cells, neural cells, MPS VI skeletal tissues	Dogs and cats
MPS I			Dogs
MPS II			Dogs
MPS IIIA			Cats (Siamese, DSH)
MPS VI			Dogs
MPS VII			
Mucolipidoses	Features of sphingolipidosis & MPS, deficiency of acetylglucosamine-1-phosphotransferases	Growth deformities; involves many tissues including: cartilage, skin, connective tissue, Kupffer cells, no hepatomegaly	Cats
Ceroid-lipofucinoses	Lipopigments (lipofuscin, ceroid) protein products	Neural cells, Kupffer cells	Dogs and cats
Niemann-Pick types A & C (Sphingomyelinosis)	Cholesterol (defective esterification)	Hepatocytes, fibroblasts	Dogs and cats
Glycogen storage diseases	Storage: glycogen	Liver, heart, skeletal muscle, kidney, CNS, RBCs: varies with defect	Dogs and cats, depending on form
GSD IA	Deficiency: Glucose-6-phosphate dehydrogenase	Fail to thrive, obtunded, hepatomegaly causing abdominal distention	Maltese dog, toy breed puppies
GSD II	α-glucosidase	Muscle, megaesophagus, neurons	Swedish Lapland dog
GSD III	Amylo-1,6-glucosidase	Like GSD IA, but mild hypoglycemia	German shepherd dog, Akita
GSD IV	α-1,4-D-glucan (glycogen branching enzyme)	Lethal perinatally, cardiac signs, skeletal muscle atrophy	Norwegian Forest cat
GSD VII	Phosphofructose kinase deficiency	RBC hemolysis (with alkalosis), skeletal muscle weakness, lacks hepatic involvement	English springer spaniel American cocker spaniels, cross breed dogs

Infection, sepsis, and endotoxemia may each cause hepatic injury and cholestasis. Clinical signs variably include hepatosplenomegaly, fever, lethargy, and jaundice. Hematologic abnormalities may include a nonregenerative anemia (chronic inflammation), leukopenia, or leukocytosis with a left shift, and toxic changes in neutrophils. Biochemical abnormalities include increased transaminase and ALP activities and variable hyperbilirubinemia. 1474 Sepsis-related hypoglycemia might be recognized. Successful therapy requires judicious provision 1475 of fluid and electrolyte support, supplemental glucose for sepsis-related hypoglycemia, and appropriate antimicrobial

coverage. Importantly, the underlying causal factor must be identified and either eliminated or controlled. Nutrition should focus on avoiding a negative nitrogen balance. Antioxidant support with thiol donors (NAC in crisis that can be used as an intravenous treatment; SAMe for more chronic oral administration) and vitamin E may be helpful.[23]

230.5.1 Box • 230-4 Conditions Predisposing to Hepatobiliary Infections Disorders in Dogs and Cats with Culture Positive Hepatobiliary Infections

230.5.1.1 Obstructed Bile Flow

Extrahepatic bile duct occlusion

Disease of the gall bladder:

- Dysmotility
- Cholelithiasis
- Cystic duct occlusion
- Cholecystic neoplasia

Parenchymal cholestasis

- Destruction of intrahepatic bile ducts: ductopenia (e.g., certain cats with chronic cholangitis/cholangiohepatitis)
- Microcholelithiasis (intrahepatic bile ducts)

Pancreatitis

230.5.1.2 Impaired Hepatic Perfusion ± Oxidant Injury:

Chronic necroinflammatory liver disease: chronic hepatitis, chronic cholangiohepatitis

Cirrhosis

Copper storage hepatopathy

Acquired portosystemic shunting

Congenital portosystemic shunting

Liver lobe torsion

Hepatic neoplasia

Primary: development of a necrotic center

Hepatocellular carcinoma, Hepatoma

Metastatic:

Lymphosarcoma, adenocarcinoma, malignant histiocytosis

Portal venous thrombosis

Pancreatitis

Trauma: automobile accident, bite wounds, penetrating wounds

230.5.1.3 Compromised Immunocompetence

Hyperadrenocorticism

Diabetes mellitus

Severe hypothyroidism

FIV/FeLV

Treatment with immunomodulatory drugs: glucocorticoids, azathioprine, methotrexate, chemotherapy

Amyloidosis

230.5.1.4 Increased Translocation of Enteric Organisms

Inflammatory bowel disease

Enteric neoplasia: lymphosarcoma, adenocarcinoma

Chronic liver disease

Extrahepatic bile duct occlusion

Reduced bowel motility

Pancreatitis

230.5.1.5 Neonatal

Omphalitis

230.5.1.6 Visceral larval migrans

Toxocara

230.5.1.7 Iatrogenic

Extension from a feeding device

Surgical infection

From Center SA[23]; in press.

In general, hepatobiliary infections, and especially focal abscesses, are uncommon. Focal abscesses may result from trauma, ascending biliary tree infection, or ischemic lesions within the liver (e.g., necrotic liver tumor, thromboembolic lesions).[23,26,29] Immunocompromised patients are at greatest risk especially for hepatic abscessation.[23] Multifocal abscess formation and microabscessation may involve a variety of organisms derived from systemic infections by hematogenous or lymphatic distribution, or by infection ascending the biliary tree.[23,27,28] Early signs of hepatic abscessation are often vague (lethargy, fever, dehydration, trembling, anorexia, vomiting, diarrhea, and weight loss). Localization of disease to the abdomen may be indicated by abdominal tenderness and hepatomegaly. Hematologic features usually include a leukocytosis with or without a left shift and toxic neutrophils, as well as monocytosis; if chronic, a nonregenerative anemia may develop. Biochemical features include increased transaminase and ALP activities, hyperglobulinemia, and sometimes, sepsis-induced hypoglycemia. Should an abscess rupture, septic peritonitis and abdominal effusion develop. Diagnosis is greatly facilitated by abdominal ultrasound, which may disclose discrete focal lesions in the hepatic parenchyma and abdominal effusion. Cytologic evaluations of abdominal effusion or aspiration from discrete parenchymal lesions usually disclose neutrophils in various conditions (necrotic, degenerative, toxic) and bacterial organisms. Culture of blood or urine may identify occult infectious agents. Submission of both aerobic and anaerobic microbial cultures from sampled lesions or effusion is critical for optimized therapy. Polymicrobial infections nearly always involve an anaerobic organism; approximately 50% of solitary hepatic abscesses in dogs appear to be polymicrobial.[23] Because anaerobes are difficult to culture, they should be suspected and treated when cytologic evaluation discloses a polymicrobial population. Further, therapy should continue even if no organisms are cultured or only a few aerobic organisms are grown. Anaerobes may potentiate infection with other organisms and alter the course of disease.[28,30,31] When causal factors remain illusive, hepatic biopsy may be indicated looking for underlying neoplasia or other primary hepatic processes predisposing to infection.

Good initial therapy for hepatic abscessation is achieved with combination of penicillin and a fluoroquinolone or an aminoglycoside. Metronidazole or clindamycin can be substituted for penicillin to provide an anaerobic spectrum.[23] Dose reduction of metronidazole by 50% is indicated in patients with jaundice or reduced hepatic function (adjusted dose for dogs and cats is 7.5 mg/kg orally, twice a day to three times a day).[23] Fluoroquinolones provide broader gram-positive coverage compared with aminoglycosides and are thought to have better penetration across an abscess wall. First-generation cephalosporins, potentiated sulfonamides, and aminoglycosides, are uniformly ineffective against anaerobes. Animals with cholestasis also should receive

ursodeoxycholic acid (10 to 15 mg/kg per day) to facilitate brisk choleresis. Hydration must be maintained to achieve this objective.

Ultrasound-guided abscess aspiration as a primary mode of abscess treatment has been successfully applied to veterinary patients.[23] This approach is recommended for several reasons: (1) as a method of confirming the diagnosis, (2) to provide time for patient stabilization before surgical exploration for liver lobe resection, and (3) because it is successful as a solitary means of therapy in a subset of patients. Major factors arguing against this technique are unsafe access, contamination or lesion depth exceeding aspiration needle length. It is always essential to anticipate a need for immediate surgical intervention when aspirating a suspected hepatic abscess in the event of abscess rupture into the peritoneal cavity.

1475

1476

Successful management of multifocal microabscessation can be accomplished with intravenous antibiotics if the involved organisms are identified and sensitivity defined. Treatment requires extensive supportive care and long-term administration (months) of a tailored antibiotic regimen targeting involved pathogens along with identification and management of the underlying predisposing cause. Disseminated sepsis should initiate a search for an underlying condition compromising immune defense.[23]

230.5.2 Hepatic Involvement in Systemic Infectious Disease

A number of systemic infectious diseases can involve the liver (see Box 230-4).[23,32] Agents with tropism for endothelium, parenchymal hepatic cells or macrophages are particularly prone to secondarily involve the liver. Infectious canine hepatitis caused by adenovirus type 1 is a unique pathogen because it is the only recognized virus with primary tropism for the liver. Along with severe hepatic necrosis and initiation of chronic hepatitis, glomerulonephritis, corneal edema, and uveitis may develop. This is currently a rare condition in North America due to high efficacy of vaccination programs.[33,34]

230.5.2.1 Granulomatous Hepatic Inflammation

Granulomatous hepatic inflammation is an uncommon diagnosis characterized by multiple discrete, sharply defined nodular infiltrates consisting of macrophage aggregates (and with or without epithelioid cells), surrounded by or intermixed with lymphocytes and plasma cells. Lesions may be focal, multifocal, or diffuse. Underlying causes include many infectious agents. Differential diagnoses that should be considered include metazoal (e.g., schistosomiasis, dirofilariasis), fungal (e.g., histoplasmosis, paecilomycosis), protozoal (e.g., visceral leishmaniasis, toxoplasmosis), bacterial (e.g., mycobacteria, *Nocardia*, *Bartonella*, *Brucella*, *Borrelia*, *Propionibacterium acnes*), and viral (e.g., feline coronavirus infectious peritonitis [FIP]) infections, and visceral larval migrans (*Toxocara* migration). Noninfectious disorders may be caused (drug reactions, lymphangiectasia, histiocytosis or histiocytic neoplasia, lymphosarcoma, and immune-mediated inflammation. The last may be associated with a positive antinuclear antibody test.[1] Until recently, causative factors have remained elusive in at least 50% of cases. However, with increased molecular surveillance for infectious causes, more definitive diagnoses are anticipated.

* Primary tumors: in order of prevalence.

230.6 HEPATOBILIARY NEOPLASIA

The most common primary and secondary types of hepatic neoplasia in the dog and cat are shown in Table 230-5. Retrospective studies show an incidence of primary hepatobiliary neoplasia in less than 1.5% of all canine and less than 2.9% of all feline neoplasms.[35–41] Hemolymphatic neoplasia in the liver is more common. The peak incidence of hepatobiliary cancer occurs at 10 to 12 years of age in both species. In cats, malignant tumors develop at a younger age than benign tumors do.[38–41,48] It remains unclear whether previously eliminated feline leukemia virus (FeLV) may induce oncogenic transformation resulting in feline hemolymphatic neoplasia in the liver. In dogs, hepatic carcinoids occur at a mean age of 8 years.[37,43] No significant breed predilections exist for primary liver cancer; however, female dogs may be predisposed to biliary carcinoma (BC), while male dogs and cats to hepatocellular carcinoma (HCC).[37,43–46] Although no evidence indicates that chronic inflammatory liver disease predisposes to HCC in dogs, cats with chronic cholangitis may have an increased predisposition to BC.

1476

1477

Primary liver tumors may be classified as hepatocellular, biliary, neuroendocrine or as sarcomas. Secondary metastasis of neoplasia to the liver is common in both species, and represents the largest proportion of hepatic cancers in dogs.[47–49] Lymphoreticular neoplasia involving the liver occurs in both species and represents the largest proportion of cancer in feline liver.[50]

Hepatic nodular hyperplasia is common in geriatric dogs, but unlike in humans, does not appear to represent a preneoplastic change. Biliary cystadenomas are considered benign tumors in older cats, and may be focal or multifocal.[51–53] Some of these may have a malignant behavior due to location in the porta hepatis. In younger cats, multiple hepatic cysts may express as a manifestation of polycystic disease, with or without renal lesions. Confusion in histologic diagnosis of these lesions with biliary cystadenomas may occur in some patients.

Clinical signs of hepatic neoplasia are often vague and nonspecific including chronic lethargy, inappetence, dehydration, PU/PD, and fever. Less commonly, vomiting, diarrhea, jaundice, and ascites may develop. PU/PD is

more commonly linked to primary liver tumors (up to 50% of dogs). Rarely, neurologic signs may occur in dogs and these reflect hypoglycemia or hepatic encephalopathy.[37,54,55] Weakness due to myasthenia gravis associated with carcinoma was described in a dog.[56] Many animals (25% dogs, 50% cats) will be asymptomatic. Finding a cranial abdominal mass or hepatomegaly is the most common physical abnormality.

Clinicopathologic features are usually vague and nonspecific. Hematologic tests may reveal a nonregenerative anemia and a neutrophilic leukocytosis reflecting neoplasia-associated inflammation. Hepatic hemangiosarcoma may produce a regenerative anemia, acanthocytosis, and schistocytosis. Mast cell tumors (MCTs) may produce eosinophilia and signs associated with release of biogenic amines.[54,55] Lymphoma may be accompanied by circulating lymphoblasts, eosinophilia, thrombocytopenia, thrombocytosis, and hematologic effects attributable to bone marrow involvement.

Biochemical changes reflect hepatocellular or biliary epithelial damage or biliary stasis (increased transaminase and ALP activities, hyperbilirubinemia, high SBA concentrations). Hepatic enzyme activity does not reflect the degree of hepatic neoplastic involvement. High SBA concentrations develop in 50% to 75% of dogs and in 33% of cats with hepatic cancer. Despite the more common prevalence of biliary neoplasia in the cat, only 33% have hyperbilirubinemic. In dogs, hypercalcemia (implying lymphoma), hyperglobulinemia, and hypoglycemia are more common. Hypoglycemia may be a dominant marker of large tumor mass (metabolic consumption) or reflect paraneoplastic phenomena due to production of an insulin-like protein.[54,55] Hypoalbuminemia, more common in dogs, may reflect a negative acute phase response, catabolism and poor nutritional intake, or hepatic insufficiency. Increased serum pancreatic lipase (PL) activity was reported in dogs (n = 6) with either pancreatic or hepatic neoplasia.[57] It was proposed that some hepatic tumors produce PL. Alpha-fetoprotein (AFP), a glycoprotein produced by fetal, neoplastic, and regenerating hepatocytes, may increase in dogs with hepatocellu-lar carcinoma, chronic hepatitis, or rapidly regenerating liver tissue.[50,58,59]

If ascites is present, fluid should be evaluated for protein, cell typers, #'s, and morphology. Imaging remains the most valuable, noninvasive method for localizing hepatic mass lesions and for detecting of overt metastasis. Abdominal radiography may show caudal and lateral displacement of the stomach. Occasionally, dystrophic mineralization of mass lesions or involved biliary tissues may be recognized. Pulmonary metastases occur late in the disease process.

Abdominal ultrasound is a better imaging modality for the detection of mass lesions, with a sensitivity (true positive, all patients with neoplastic lesions) ranging between 20% to 84% depending on operator, equipment and tumor type.[60,61] Although echogenicity and distribution can suggest a tumor type, broad overlap of patterns occur and findings do not closely correlate with histologic type.[62] Lesions may be localized or diffuse, hypo-, hyper-, or of mixed echogenicity; target lesions (hypoechoic margin surrounding a hyperechoic core) may be observed with carcinomas and other tumor types. Most variable in appearance are lymphomas as these may assume nearly any echogenic appearance or remain indiscernible despite diffuse hepatic involvement. Ultrasound may fail to detect neoplasia, and mass lesions from other causes may be erroneously assumed to be neoplasia.[63] Hematomas acquired from needle aspiration or Tru-Cut® biopsy sampling may subsequently be observed as mass lesions. Doppler (color flow) assessment of the mass may show vascularization more consistent with a tumor versus a benign process.[50,64] Computed tomography (CT) or magnetic resonance imaging (MRI) can provide information valuable in tumor staging and planning for attempted surgical resection.

Collection of cells by fine needle aspiration or tissue (via Tru-Cut® needle, laparoscopic, or surgical biopsy) for histopathology is required for definitive diagnosis.[65,66] Cytologic diagnoses of lymphoma, MCT, and carcinomas

may be accomplished in some cases. Bleeding tendencies must be considered before invasive tissue sampling. Usually, fine needle aspiration poses little threat.

Treatment and prognosis of different forms of hepatic neoplasia depends on its distribution, localization, and tumor type. Removal of focal mass lesions or liver lobe resections are recommended for neoplasia restricted to the liver. Tumors involving the porta hepatis cannot be resected. The considerable regenerative capability of the liver can permit successful resection of up to 80% of the liver if the remaining tissue is normal functionally and critical supportive care provides fluid, electrolyte, glucose, water-soluble vitamin, and coagulation factor support.[67] Caution is warranted in diagnosing apparent metastatic disease on the basis of gross appearance of the liver at the time of surgery, because hyperplastic nodules may be mistaken for cancer. Mass resection may offer palliation in the circumstance of a bleeding mass, despite irrefutable evidence of metastasis. Biliary tree diversion (biliary enteric anastomoses) should be considered for obstructive lesions involving the extrahepatic biliary structures because long-term palliation is possible. Chronic biliary tree occlusion results in cirrhosis within 6 to 8 weeks.

A fair to good prognosis may follow excision of focal canine HCC and benign feline tumors. However, dogs with BC and cats with malignant tumors have a poorer prognosis. HCC can be confusing because it may present as diffuse, multifocal, or solitary lesions. Histopathologic subtype and anaplastic characteristics also influence whether a HCC will metastasize. Metastasis is highest (100%) with diffuse HCC and lowest (37%) with solitary mass HCC. After surgical resection of HCC, a median survival time (MST) of 377 days was reported (n = 18).[42] Adjunctive, postoperative chemotherapy (5-fluorouracil, cisplatin, actinomycin D) has not been shown to provide significant benefit in dogs. However, one of four dogs treated with mitoxantrone had a complete response.[68] No comparable information is available for cats.

Biliary carcinoma shows a high metastatic rate in both dogs and cats (56% to 88% and 67% to 78%, respectively).[48,69] Surgical resection is more difficult than for HCC due to multifocal or diffuse extension and involvement of the porta hepatis. Little information exists regarding adjunctive chemotherapy. In cats, surgical resection of biliary adenomas or myelolipomas may provide several years of tumor-free survival or cure. Despite the benign character of these tumors, removal is recommended because malignant transformation has been suggested.[49]

1477

1478

Postoperative adjunctive chemotherapy has been beneficial in inducing remission and prolonging survival in dogs with hepatic hemangiosarcoma. Surgery is indicated for removal of bleeding or large resectable masses. Chemotherapeutic protocols include a combination of vincristine, doxorubicin, and cyclophosphamide.[50]

Hepatic carcinoids and lymphosarcomas in dogs have a high metastatic rate (86% to 93%). Carcinoids are a rare and aggressive neuroendocrine tumor.[35,37,43]

Hepatic tumors metastasize first to regional lymph nodes then lung, and peritoneum in the dog and peritoneum in the cat. Biliary tumors in the cat may extend into the pancreas. Metastatic extension to brain, spinal cord, bone, kidney, adrenal gland, and spleen is less common in each species.

Canine MCT involving the liver can be controlled with cyclophosphamide, vinblastine, and prednisone.[50,70] Many protocols are recommended for control of lymphoma in dogs and cats; most include vincristine, cyclophosphamide, and prednisone, with variable combinations of L-asparaginase, methotrexate, and doxorubicin.

Radiation therapy is not a feasible option for hepatic cancers, owing to the exquisite sensitivity of this organ to even low amounts of radiation.[71] Although liver transplantation, directed delivery of chemotherapeutic agents (intra-arterial chemotherapy), transarterial chemoembolization, and immunotherapeutic regimes using a-FP as a tumor-specific antigen have been used in humans with HCC, these have not been explored in animals.[72,73]

231 CHAPTER • 231 Diseases of the Gallbladder and Extrahepatic Biliary System

Michael D. Willard

Theresa W. Fossum

231.1 ANATOMY

Bile is formed by hepatocytes and discharged into the canaliculi lying between the hepatocytes. Canaliculi unite to form interlobular ducts, which ultimately merge to form lobar or bile ducts. The gallbladder plus the hepatic, cystic, and common bile ducts constitute the extrahepatic biliary system. Bile drains from the bile ducts into the cystic and common bile ducts and is stored and concentrated in the gallbladder (Figure 231-1). The gallbladder lies between the quadrate lobe of the liver medially and the right medial lobe laterally.[1] It is a pear-shaped organ that, in a medium-sized dog, normally holds approximately 15 mL of bile. The rounded end of the gallbladder is the fundus. Between the neck of the gallbladder (i.e., the tapering end leading into the cystic duct) and the fundus is the body.

The cystic duct extends from the neck of the gallbladder to the junction with the first tributary from the liver.[1] From this point to the opening of the biliary system into the duodenum, the duct is termed the *common bile duct*. The common bile duct runs through the lesser omentum for approximately 5 cm and enters the mesenteric wall of the duodenum. The canine common bile duct terminates in the duodenum near the opening of the minor pancreatic duct. This combined opening of the minor pancreatic duct and common bile duct is the major duodenal papilla. The feline common bile duct usually joins the major pancreatic duct before entering the duodenum.[1]

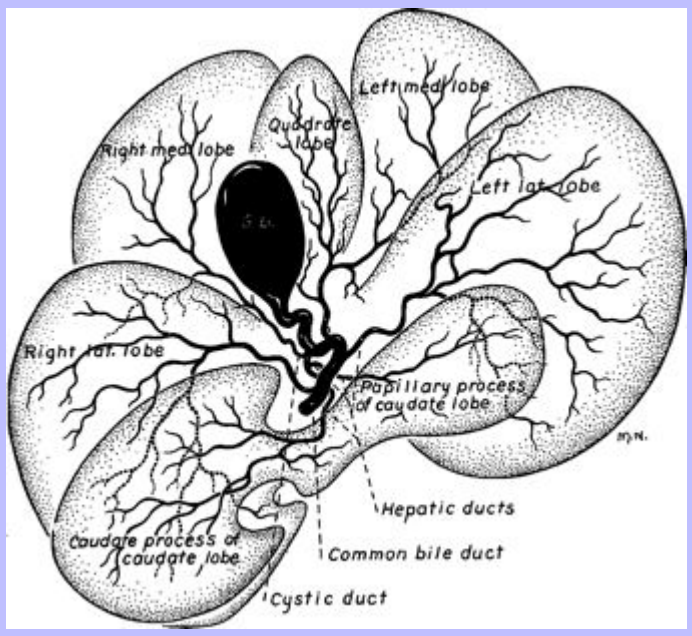
231.2 PHYSIOLOGY

Bile primarily contains water, conjugated bile acids, bile pigments, cholesterol, and inorganic salts. Over 90% of bile salts are reabsorbed from the intestinal tract, transported back to the liver via the portal vein, and re-excreted (i.e., enterohepatic circulation). Bilirubin and biliverdin produce the typical yellow color of bile. Bile is continually secreted into the gallbladder, where it is stored and modified. Gallbladder emptying is normally induced by neural (vagal parasympathetics) and humoral (cholecystokinin) stimuli. Parasympathomimetic drugs and magnesium sulfate[2] cause gallbladder contraction, whereas anticholinergic drugs and somatostatin inhibit contraction.[1]

231.3 DIAGNOSTIC TOOLS FOR EVALUATING THE GALLBLADDER AND BILE DUCTS

Icterus, vomiting, abdominal pain, and ascites are all consistent with biliary tract dysfunction. Complete blood count (CBC), serum biochemistry profile, and urinalysis are indicated if biliary tract dysfunction is suspected. The CBC inconsistently reflects cholecystic inflammation. Increased alanine aminotransferase (ALT) is common if inflammation ascends into the hepatic parenchyma. Increased serum alkaline phosphatase (SAP), with or without hyperbilirubinemia, is typical in extrahepatic biliary tract obstruction (EHBO)[3] and inflammatory disease ascending from the biliary tract. Cats tend to have lesser elevations of SAP than dogs.

Figure 231-1 Anatomy of the canine gallbladder. (From Evans HE, Christensen GC: Miller's Anatomy of the Dog, 3rd ed. Philadelphia, WB Saunders Co, 1993, p 750.)



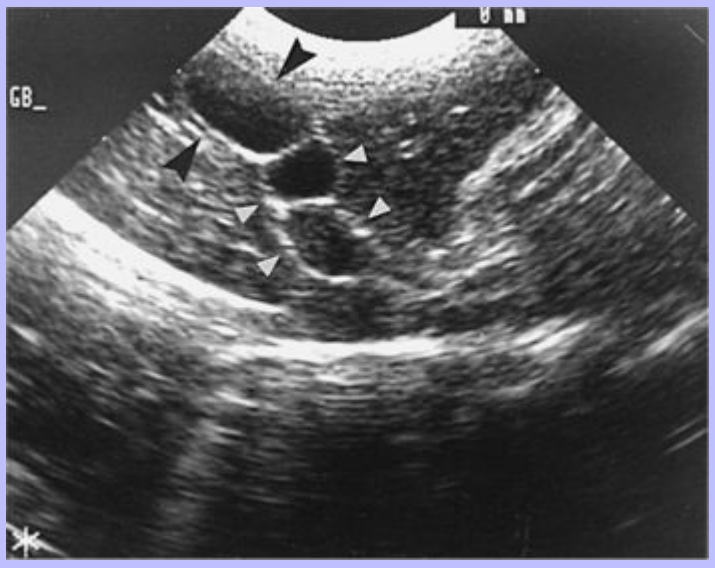
Hypercholesterolemia may occur secondary to EHBO. Bilirubinuria occurs before hyperbilirubinemia. Imaging, surgery, or both are usually required to differentiate icterus due to hepatic disease versus biliary tract disease.

Abdominal radiographs may reveal radiodense objects (e.g., gallstones) or air in the gallbladder. Animals with EHBO due to pancreatitis may have a soft tissue mass or poor serosal detail in the region of the pancreas. Contrast radiographs of the biliary tree are rarely useful, and endoscopic retrograde pancreatography is rarely performed in icteric animals.

Ultrasonography is the most useful nonsurgical technique to distinguish hepatic parenchymal from biliary tract disease. It can identify abnormalities within the lumen of the gallbladder (e.g., stones, tumors, flocculent material) and most biliary tract obstructions (Figure 231-2).[3] Finding "sludge" is not informative because many normal dogs have this finding.[4] Anorexic animals often have marked cholecystic enlargement, which can be misdiagnosed as obstruction. Dilatation of the gallbladder plus loss of the tapering of the gallbladder neck typically occur within 24 hours of ligation of the bile duct. This is followed by dilatation of the common duct at 48 hours and of the extrahepatic ducts at 72 hours. Similar changes occur in the intrahepatic bile ducts within 1 week.[5] The common bile duct is typically less than 3 mm in diameter in medium-sized dogs[6] and less than 2.5 mm in cats.[3] One study found that 28 cats without EHBO had a common bile duct 4 mm or less in diameter, whereas a common bile duct greater than 5 mm in diameter meant EHBO in six of seven cats.[7] Distension of the gallbladder plus the common bile duct was the most common finding in 22 cats.[8] If the clinician is unsure whether EHBO is present after performing ultrasonography, repeating the examination in 2 to 4 days or after

inducing gallbladder contraction (e.g., feeding a high-fat meal) is often definitive. However, loss of elasticity of the bile ducts may occur as a result of aging, inflammation, or chronic obstruction (especially in cats), and some ducts never return to their original diameter after obstruction.[5,6] Rarely, EHBO will not be diagnosed until laparoscopy or laparotomy.

Figure 231-2 Distention and convolution of the gallbladder body *(black arrowheads)* and neck *(white arrowheads)* in a cat with common bile duct obstruction. (Courtesy of Dr. L. Homco, Texas A&M University.)



Gallstones are typically identified ultrasonographically as hyperechoic foci or by the observation of acoustic shadowing originating from the gallbladder.[5] Sediment (sometimes referred to as *sludge*) is occasionally noted in the gallbladder, but its significance is uncertain. Supposedly, bile becomes progressively thicker as water is absorbed during biliary stasis.

Soft tissue changes of the gallbladder (e.g., tumors, granulation tissue, congenital defects) may be seen ultrasonographically. Cholecystitis may cause gallbladder wall thickening, edema, or both, which can produce a layered or "double-wall" ultrasonographic appearance[5]; however, one cannot reliably diagnose cholecystitis ultrasonographically. Finding a stellate or striated pattern within the gallbladder with immobile contents is suggestive of mucocele.[9]

Bile (for culture or cytologic examination) can be aspirated from the gallbladder by ultrasound-guided fine-needle aspiration using a 22-to 25-gauge needle.[10] As much bile as possible is withdrawn to lessen the likelihood of subsequent bile leakage into the abdomen. This procedure appears to be relatively safe, although vagal-induced severe bradycardia and other problems have occurred in people.[1] Aerobic and anaerobic cultures of bile (and hepatic parenchyma) are recommended if bacterial cholecystitis is suspected.

Laparoscopy or exploratory laparotomy should be performed in animals with suspected leakage of bile into the abdomen, as well as those with EHBO, neoplasia, parasites, stones, infiltrates, and other mass lesions of or within the biliary tract. Laparoscopy can be particularly valuable in helping the clinician decide if exploratory surgery is warranted. During exploration, patency of the common bile duct must be ensured by compressing the gallbladder or catheterizing the duct. Readers are referred to surgery texts for detailed information regarding extrahepatic biliary tract surgery.[11] Nuclear scintigraphy is rarely used to define canine or feline biliary disease, owing to the need for specialized equipment and facilities.

231.4 SPECIFIC PROBLEMS SEEN WITH GALLBLADDER AND BILIARY TRACT DISEASE

Vomiting, icterus, and anorexia are common in animals with inflammatory or obstructive biliary tract disease.[12,13] Fever and abdominal discomfort also occur, but not as consistently. Icterus is often helpful for localizing the problem to the biliary tract. After hemolytic disease is eliminated, ultrasonography helps distinguish hepatic parenchymal from biliary tract disease. Ascites may occur owing to leakage of bile into the peritoneal cavity. Bilious effusions are obvious because the fluid looks like bile. If one is unsure whether abdominal fluid is bilious or bile stained, bilirubin concentrations in serum and in effusion should be compared. Bilious effusions have fluid bilirubin concentrations greater than serum concentrations.

1479
1480

Acute abdomen (i.e., shock, sepsis, pain due to abdominal disease) may be caused by leakage of bile into the peritoneal cavity, particularly if the bile is septic. Hematemesis is uncommon in animals with cholecystic disease, but intracystic bleeding may allow blood to exit into the duodenum, where it is refluxed into the stomach and vomited.

231.5 SPECIFIC DISEASES OF THE GALLBLADDER

231.5.1 Obstructive Disease

Pancreatic disease is the most common cause of canine EHBO,[3] whereas tumors and inflammatory disease of the biliary tract, pancreas, or both are the most common causes in cats.[8] Stones can cause EHBO, but they do so uncommonly.[14] Therefore the prognosis for dogs with EHBO is generally much better than it is for cats.

Pancreatitis may cause scar formation in or around the duct or compress the duct by inflamed tissue, abscesses, or cysts. Treatment of EHBO secondary to benign pancreatitis initially consists of medical management of the pancreatitis. If this is unsuccessful or if ascending bacterial infection is suspected, cholecystoduodenostomy or cholecystojejunostomy may be considered but should generally be avoided unless absolutely necessary. In extremely ill animals with EHBO that cannot undergo surgical exploration, temporary decompression of the gallbladder with a Foley catheter or a self-retaining accordion catheter may be warranted.

Neoplasia (especially biliary tract or pancreatic adenocarcinomas) may cause EHBO. Surgery for pancreatic neoplasia is generally unrewarding, because most such tumors are malignant. Cholecystojejunostomy may be palliative if the intestinal lumen is patent. Pancreatic-duodenal resection (i.e., Billroth II) is possible; surgical cures are unlikely, whereas morbidity may be substantial. Biliary, intestinal, hepatic, or lymph node malignancy may also obstruct the bile ducts; biopsy is imperative to obtain a diagnosis. The prognosis is typically poor; however, chemotherapy benefits some animals with lymphosarcoma.

Choleliths (see Nonobstructive Disease) that obstruct the common bile duct should be removed. Cholecystectomy is the treatment of choice when clinical signs are secondary to cholelithiasis.[13] If stones are present in the common bile duct, the duct can be catheterized via the duodenum and the stones flushed into the gallbladder. Alternatively, enlarged bile ducts can be incised (choledochotomy) and the stones removed; however, care is needed when closing the common bile duct to avoid iatrogenic stricture formation. Much greater mortality occurs in people with cholelithiasis when a choledochotomy is performed versus cholecystectomy.

A gallbladder mucocele is an abnormal accumulation of inspissated mucus that distends the gallbladder and often causes some degree of EHBO.[9] Affected dogs will usually be icteric and have abdominal pain plus increased ALT, SAP, or bilirubin. Mucoceles typically cause a striated or stellate appearance on ultrasound with immobile bile. Cocker spaniels might be over-represented. Infection sometimes occurs. Left untreated, necrosis of the gallbladder with subsequent rupture may occur. Cholecystectomy seems the preferred therapy. Miscellaneous causes of EHBO include diaphragmatic hernia[15] and biliary pseudocysts.[16]

231.5.2 Nonobstructive Disease

Cholecystitis (i.e., inflammation of the gallbladder) usually involves the associated bile ducts. It is typically due to a bacterial infection caused by bacteria ascending from the intestine via the common bile duct or by hematogenous seeding, and it can often be cured with antibiotics. However, if cholecystitis recurs repeatedly despite appropriate use of antibiotics, cholecystectomy is usually curative. Cholecystitis may take one of several courses.

Bacterial cholangitis and cholangiohepatitis occur if the infection ascends the biliary tree into the liver. This appears to be more common in cats than in dogs, but Shetland sheepdogs may have a higher than expected incidence. Any bacteria may be responsible; *Escherichia coli* seems especially common. These animals often present to veterinarians because of icterus, anorexia, vomiting, or a combination of these symptoms. Fever is uncommon. Increased serum ALT, SAP, and bilirubin are typical, but neutrophilia is inconsistent. Imaging is seldom diagnostic but helps eliminate other diseases. Cats with a gallbladder wall greater than 1.0 mm thick typically have histologic abnormalities of the gallbladder, but cats with a less thick gallbladder wall may also have disease.[17] Fine needle aspirate of the gallbladder with subsequent cytology of bile may reveal bacteria (Figure 231-3). Hepatic biopsy with aerobic and anaerobic culture of bile and hepatic parenchyma is indicated. The prognosis is variable, but good results are expected when the correct antibiotics are promptly administered. Enrofloxacin plus amoxicillin is reasonable until culture results are available. Vitamin K_1 should be administered if coagulopathy is suspected.

Necrotizing cholecystitis occurs when a bacterial infection severely damages the gallbladder wall, sometimes rupturing it (Figure 231-4) and spilling bile into the abdomen.[18] This usually causes generalized septic peritonitis. If the bile is inspissated, rupture causes spillage of a relatively thick, gelatinous mass into the cranial abdomen, producing a localized peritonitis. These animals tend not to become as sick as quickly as those with diffuse peritonitis. Sometimes pain can be localized to the anterior abdomen. If diagnosed before the gallbladder ruptures, signs are similar to those of localized peritonitis. Adhesions or fistulous tracts around the gallbladder occasionally occur. Diagnosis is usually made by ultrasonography or exploratory laparotomy. Surgical exploration should be performed once the animal is stable. Treatment consists of cholecystectomy, antibiotics, and appropriate therapy for peritonitis. Salvaging the gallbladder by closing the defect is inappropriate because the wall is typically necrotic and will dehisce. The common bile duct must not be

ligated when the gallbladder is removed. The mortality rate was 39% in a study of 19 dogs with necrotizing cholecystitis; delayed diagnosis probably contributed to this high mortality.[18]

Figure 231-3 Photomicrograph of bile obtained by cholecystocentesis showing bacteria.

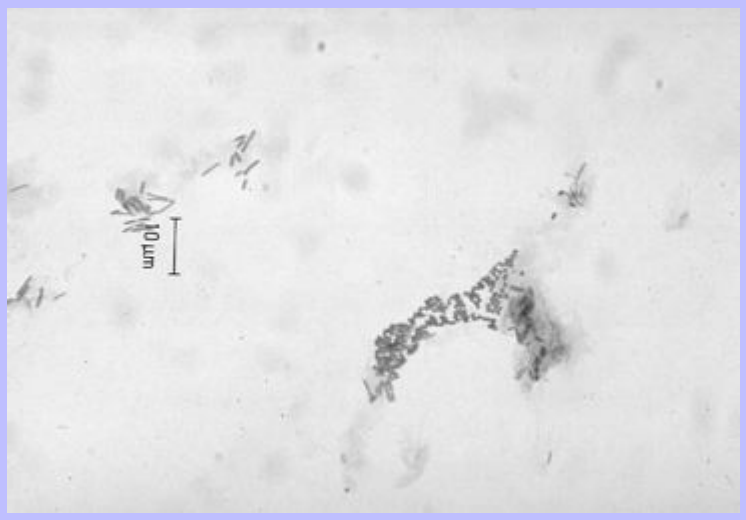


Figure 231-4 Photograph of a ruptured gallbladder that has been resected from a dog. Rupture was spontaneous and was due to necrotizing cholecystitis. Forceps are in the cystic duct.

Emphysematous cholecystitis occurs when gas-forming bacteria infect the gallbladder and gas fills the lumen or invades the wall (tympanic and emphysematous cholecystitis, respectively).[19] Once considered pathognomonic of diabetes mellitus, emphysematous cholecystitis can develop in any animal. Signs may be similar to those described for bacterial and necrotizing cholecystitis. Plain radiographs are diagnostic (Figure 231-5), and treatment consists of antibiotics. Knowing that gas-forming bacteria (e.g., *E. coli, Clostridium perfringens*) must be responsible helps guide antibiotic selection (e.g., enrofloxacin plus amoxicillin).

Choleliths are often fortuitous findings at necropsy or during imaging.[1] They often cause no problems (Figure 231-6); however, they may be associated with cholecystitis or rupture.[13] If found in an animal with biliary tract disease, they should be removed. Although people commonly develop dietary-induced cholesterol gallstones, canine gallstones usually contain bilirubin, calcium, and mucin.

Parasites of the gallbladder, bile ducts, or both are seldom diagnosed. *Platynosomum fastosum* (previously *P. concinnum*) is a fluke principally found in animals from Florida, Hawaii, and the Caribbean. It typically infects cats that eat lizards or toads (i.e., a second intermediate host). The fluke may ultimately be found in the gallbladder, bile ducts, or both, where it may be asymptomatic or cause fibrosis, obstruction, or both. Signs of infection can be similar to those of cholecystitis. Diagnosis is by ultrasonography or by finding ova by fecal sedimentation examination (not fecal flotation), assuming that complete biliary tract obstruction does not occur. Therapy may be attempted with praziquantel (20 mg/kg subcutaneously, once a day for 3 days). Prognosis is uncertain, but severe hepatic disease warrants a guarded prognosis.[1] *Amphimerus pseudofelineus* has also been associated with cholangitis, cholangiohepatitis, and distention of the feline common bile duct.[20] High-dose (40 mg/kg) praziquantel therapy administered orally once a day for 3 days reportedly eradicated the infection. *Metorchis conjunctus* and *Eurytrema procyonis* may also be found in the feline biliary tract.

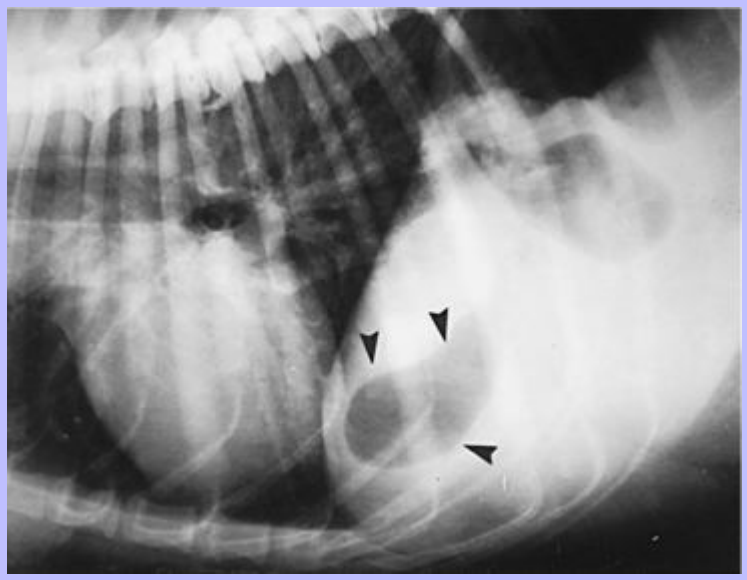

Figure 231-6 Lateral radiograph of a dog showing mineral densities in the region of the gallbladder *(arrows)*. These were gallstones that were not causing clinical disease in this dog.

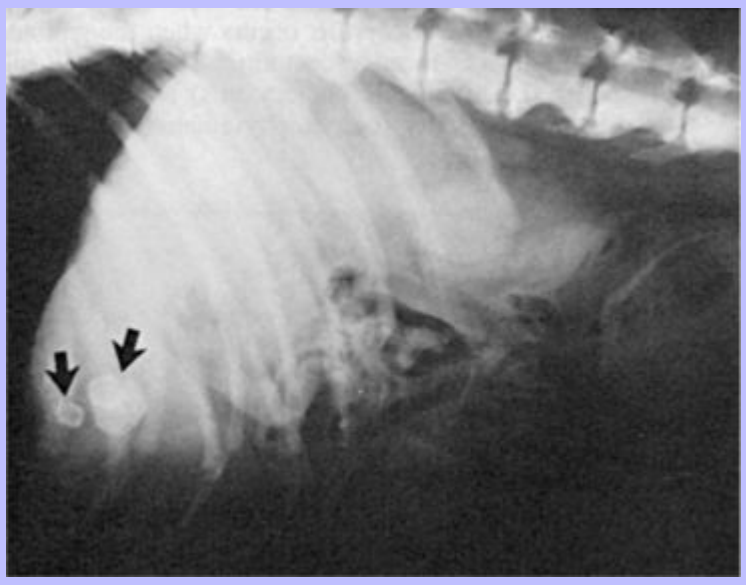

Neoplasia of the gallbladder or extrahepatic biliary tract is rare. Bile duct carcinomas have been reported in cats and dogs.[19] Metastasis of bile duct carcinomas commonly occurs before clinical signs manifest; therefore surgery is rarely curative. Surgical therapy of cholecystic tumors may be curative if no metastasis exists.

Congenital dilatation of intrahepatic and extrahepatic bile ducts may occur without obstruction in dogs with Caroli's disease. Affected animals are generally less than 3.5 years old and usually experience vomiting, polyuria, anorexia, ascites, and increased hepatic enzymes. The gallbladder and common bile duct are generally normal in size. Renal fibrosis and cystic changes are common in affected animals.[21]

231.5.3 Rupture of the Gallbladder or Extrahepatic Biliary Ducts

Extrahepatic biliary duct or gallbladder rupture may be iatrogenic or associated with blunt abdominal trauma, cholecystitis, or obstruction secondary to stones, neoplasia, or parasites. Trauma usually causes rupture of the bile duct rather than the gallbladder. Ductal rupture probably occurs when a force is applied adjacent to the gallbladder sufficient to cause a shearing force on the duct. The most common site of ductal rupture appears to be the common bile duct just distal to the entrance of the last hepatic duct; however, rupture may occur in the distal common bile duct, cystic duct (rare), or hepatic ducts. Gallbladder rupture is more commonly associated with necrotizing cholecystitis or cholelithiasis, with or without obstruction of the common bile duct.[18]

1481

1482

Early diagnosis of biliary tract rupture is imperative. Leakage of infected bile causes clinical signs of bile peritonitis to develop quickly. In a study of 24 dogs and two cats with biliary tract rupture, there was 54% mortality, which was limited to animals with infected bile. *E. coli* was the bacterium most commonly cultured

from infected animals.[12] Ascites and icterus may be the only signs in dogs with sterile bile in the peritoneal cavity due to traumatic rupture; however, necrosis and changes in mucosal permeability secondary to the bile can allow secondary bacterial infection.[19] Delayed diagnosis of a ruptured biliary tract results in necrotic tissues and adhesions, which complicate surgical repair. Diagnostic peritoneal lavage may assist in the early diagnosis of sterile bile peritonitis.

Surgical treatment for a ruptured common bile duct involves repair of the duct or biliary diversion. Repair is often possible if the rupture is diagnosed early, but it becomes difficult once adhesions develop. In such cases, cholecystojejunostomy is generally easier and safer. Ruptured hepatic ducts are usually ligated. Gallbladder rupture should be treated by cholecystectomy.

231.5.4 Miscellaneous Findings

Cystic mucinous hypertrophy is occasionally found in older animals, either at necropsy or during ultrasonography. It is not clearly associated with disease, although progestational drugs may produce it.[1] Unless evidence of significant gallbladder dysfunction exists, this lesion does not warrant further evaluation. Congenital defects of the gallbladder are occasionally observed. Bifid gallbladders have been reported in cats, although their significance is unknown. Nonbiliary tract disorders may also produce cholecystic lesions. Gallbladder edema is reportedly common in infectious canine hepatitis. In other diseases, however, gallbladder lesions are seldom significant. Even in canine salmonellosis, the gallbladder is rarely important as a reservoir of infection.

232 CHAPTER • 232 Canine Exocrine Pancreatic Disease

David A. Williams

Jörg M. Steiner

Exocrine pancreatic disease occurs commonly in dogs. Pancreatitis is by far the most common disorder, followed by pancreatic adenocarcinoma, exocrine pancreatic insufficiency (see Chapter 234), and other less commonly observed conditions.

232.1 PANCREATITIS

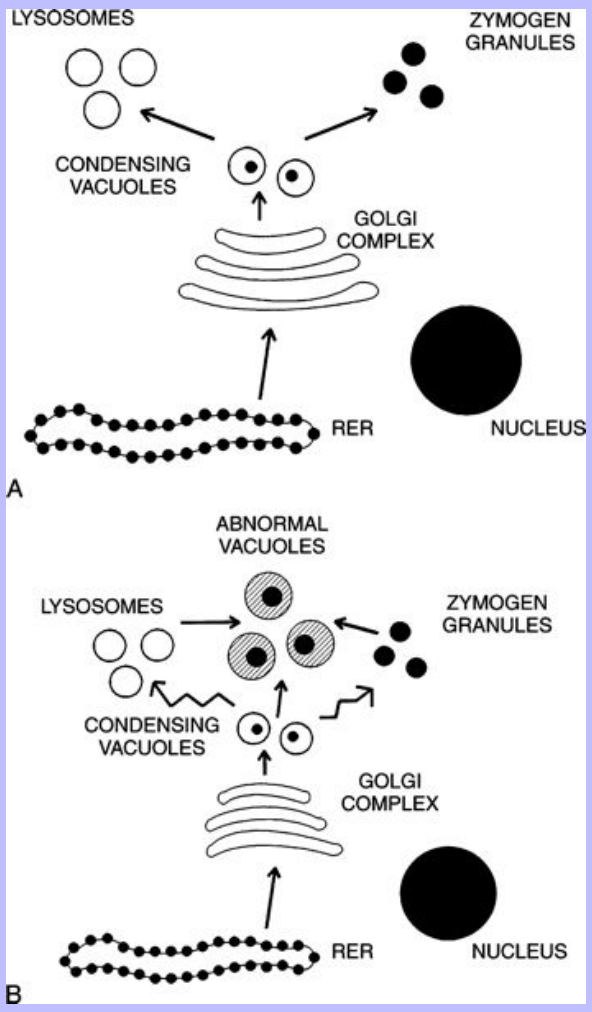
Classification of inflammatory disease of the pancreas in human beings has been standardized and simplified during the last two decades; however, the same is not true in veterinary medicine, and different authors classify pancreatitis differently. The following classification is based on the system currently used in humans.[1] *Acute pancreatitis* refers to pancreatic inflammation that, after removal of the inciting cause, is completely reversible.[1] Chronic pancreatitis, on the other hand, is a long-standing inflammation of pancreatic tissue associated with irreversible histopathologic changes, most importantly fibrosis and atrophy.[1] Acute and chronic pancreatitis cannot be differentiated clinically and can be mild or severe; however, chronic cases are more commonly mild and acute cases more commonly severe. Although mild pancreatitis is associated with few systemic effects, minimal pancreatic necrosis, and a low mortality, severe pancreatitis is characterized by extensive pancreatic necrosis, multiple organ involvement, and a poor prognosis.[1] Another classification parameter is the presence or absence of pancreatic complications, such as acute fluid accumulations around the inflamed pancreas (previously also known as *pancreatic phlegmon*), infected necrosis, pancreatic pseudocyst, and pancreatic abscess.[1] Classification based on cause is desirable but unfortunately cannot be achieved in most cases.

Numerous experimental procedures including hyperstimulation by administration of caerulein, carbamylcholine, or scorpion venom; obstruction of the pancreatic duct; intraductal injection of bile, fatty acids, or enzymes; pancreatic ischemia; and certain dietary manipulations all induce pancreatitis in dogs.[2] Some of these factors may also play a role in the development of spontaneous pancreatitis.[2,3] Ultimately, pancreatitis develops as a consequence of autodigestion of the pancreas resulting from premature zymogen activation within acinar cells. An early event in many experimental models of pancreatitis is abnormal fusion of lysosomes and zymogen granules (Figure 232-1). Lysosomal proteases, such as cathepsin B, are capable of activating trypsinogen, and the low pH in the fusion vacuoles also favors trypsinogen activation.

Several mechanisms are in place that prevent autodigestion of the pancreas by the enzymes it secretes. First, proteolytic and phospholipolytic enzymes are synthesized, stored, and secreted in the form of catalytically inactive zymogens. These zymogens are activated by enzymatic cleavage of a small peptide—the activation peptide—from the amino-terminal of the polypeptide chain.[2] Enzymes from several sources, including some lysosomal proteases, are capable of activating pancreatic zymogens, but ordinarily activation of zymogens does not occur until they are secreted into the small intestine. The enzyme enteropeptidase, which is synthesized by duodenal enterocytes, is particularly effective at cleaving the activation peptide from trypsinogen and plays a crucial role in the activation of digestive enzymes.[2] Active trypsin subsequently cleaves the activation peptide from other digestive zymogens. During synthesis, processing, storage, and secretion, digestive enzymes are strictly segregated from other, potentially damaging, cellular enzymes, such as lysosomal enzymes.[2] Should

spontaneous intrapancreatic activation of trypsinogen occur, at least two mechanisms help to limit activation of other zymogens. Trypsin is quite effective at hydrolysing itself, so that activation of small amounts of trypsin tends not to be catastrophic. However, should significant activation occur, acinar cells contain a specific trypsin inhibitor—pancreatic secretory trypsin inhibitor (PSTI)—that is synthesized, segregated, stored, and secreted along with the digestive enzymes (Table 232-1).[2] PSTI is believed to inhibit trypsin activity should there be significant activation of trypsinogen within the acinar cell or duct system.[2] However, this mechanism fails at the low pH in the fusion vacuoles.

Figure 232-1 Normal **(A)** and abnormal **(B)** intracellular routing of digestive and lysosomal enzymes by the pancreatic acinar cell. The abnormal intracellular routing of digestive enzymes during pancreatitis results in mixing of zymogens and lysosomal proteases in intracellular vacuoles. Subsequent activation of zymogens by lysosomal proteases is considered to initiate the development of pancreatitis.



Once intracellular and intraductal activation of trypsinogen to trypsin takes place, further activation of all zymogens (particularly proelastase and prophospholipase) will amplify pancreatic damage. Activation of progressively larger amounts of protease and phospholipase within the gland is associated with progression of mild edematous pancreatitis to hemorrhagic or necrotic pancreatitis with multisystem involvement and consumption of plasma protease inhibitors.[2,4]

Plasma protease inhibitors (see Table 232-1), particularly α-macroglobulins, are vital in protecting against the otherwise fatal effects of proteolytic enzymes in the vascular space.[2,4] Dogs die rapidly from acute disseminated intravascular coagulation (DIC) and shock once α-macroglobulin is depleted, because free proteases concurrently activate the kinin, coagulation, fibrinolytic, and complement systems.[2,4] Binding of proteases by α-macroglobulin results in a conformational change that allows the complex to be rapidly cleared from the plasma by the reticuloendothelial system (RES). This removal of α-macroglobulin–bound proteases by the RES is important because proteases bound to α-macroglobulin retain catalytic activity, particularly against low molecular weight substrates.

The primary function of α_1-proteinase inhibitor (α_1-PI) is to inhibit neutrophil elastase during inflammation (see Table 232-1). Although pancreatic proteases do bind to α_1-PI and are effectively inhibited, the binding is reversible and the availability of α_1-PI during pancreatitis is not life saving.[2] Alpha$_1$-PI probably serves as a transient inhibitor and intermediary in the transport of proteases to α-macroglobulin, particularly in the extravascular space, into which the large α-macroglobulin molecules cannot permeate.

Once enzyme activation is initiated, numerous inflammatory mediators and free radicals are important in the progression of pancreatitis.[4,5] These mediators are mostly released from neutrophils and macrophages and include tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-2, IL-6, IL-8, IL-10, interferon-α (INF-α), INF-γ, nitric oxide (NO), and platelet activating factor (PAF).[5]

232.1.1 Cause

The inciting cause of pancreatitis in the dog is usually unknown, but the following potential causes and risk factors should be considered.[2] It has been suggested that pancreatitis is more prevalent in obese animals,[2] and it has been shown that the disease is less severe when induced in lean dogs.[2] Evidence also shows that a low-protein high-fat diet induces pancreatitis, and that pancreatitis is more severe when induced in dogs being fed a high-fat diet.[2]

Hyperlipidemia, often grossly apparent, is common in dogs with acute pancreatitis, and may develop as a result of abdominal fat necrosis or may be a cause of the disease in some cases. Some familial hyperlipidemias in human beings are associated with frequent episodes of pancreatitis that respond to control of serum triglyceride concentrations. It is widely believed that the high prevalence of pancreatitis observed in Miniature Schnauzers may be related to idiopathic hyperlipidemia.[2]

Hereditary pancreatitis is well-documented in human beings. Several mutations of the cationic trypsinogen gene (and some other genes) have been identified, the most prevalent being replacement of the arginine in position 117 with a histidine (R117H) or replacement of the asparagine in position 21 with isoleucine (N21I).[6] The two mutations mentioned lead to conformational changes that protect trypsin from autodigestion. As a consequence, prematurely activated trypsin persists and can trigger activation of other zymogens.[6] The high

prevalence of pancreatitis in the Miniature Schnauzer suggests a possible hereditary component; however a recent study failed to identify any mutations in the cationic trypsinogen gene in this breed.

Table • 232-1 Major Protease Inhibitors in Canine Pancreas and Plasma

INHIBITOR	PANCREATIC SECRETORY TRYPSIN INHIBITOR (PSTI)	α_1-PROTEINASE INHIBITOR (α_1-ANTITRYPSIN) (α_1-PI)	MACROGLOBULINS (α-M_1 AND α-M_2)
Principal locations	Pancreas, pancreatic juice	Plasma, intercellular space	Plasma
Approximate molecular weight	6000	55,000	750,000
Specificity	Trypsin only	Broad spectrum (serine proteases)	Broad spectrum (serine and other proteases)
Inhibition	Temporary (slowly degraded by trypsin)	Transient (transfers enzyme to α-M)	Irreversible (permanent trap for captured enzyme)
Function	Inhibits intrapancreatic autoactivation of trypsin	Readily diffusible inhibitor present in the intercellular space	Traps proteases prior to removal by reticuloendothelial system (RES)

More than 50 drugs and drug classes have been implicated as a cause of pancreatitis in human beings, although absolute proof of a causal relationship is often lacking.[7] Suspect drugs that are also commonly used in veterinary medicine include L-asparaginase, azathioprine, estrogen, furosemide, potassium bromide, salicylates, sulfonamides, tetracyclines, thiazide diuretics, and vinca alkaloids.[2,8] Corticosteroids have recently been removed from the list of drugs that may induce pancreatitis in human beings. There is little credible evidence that glucocorticoid administration causes pancreatitis in dogs with the possible exception of the use of high doses in association with spinal trauma (e.g., surgical intervention for intervertebral disc disease). Nonetheless, it is probably wise to discontinue the use of any drug in patients with pancreatitis of undetermined cause unless a specific indication for continued use exists and no alternatives are available.

Administration of cholinesterase inhibitor insecticides and cholinergic agonists has been associated with the development of pancreatitis, probably by causing hyperstimulation.[2] Scorpion stings cause pancreatitis in human beings in Trinidad, and experimental administration of scorpion venom to dogs also elicits pancreatitis. Zinc toxicosis has also been reported to cause pancreatitis in the dog. Also, both spontaneous or iatrogenic hypercalcemia may cause pancreatitis in dogs.[2]

Experimental obstruction of the pancreatic ducts produces atrophy and fibrosis, although inflammation and edema may also develop when pancreatic secretion is stimulated.[9] Clinical conditions that may lead to partial or complete obstruction of the pancreatic ducts include biliary calculi, sphincter spasm, edema of the duct or duodenal wall, neoplastic conditions, parasites, trauma, and surgical interference. Biliary calculi are a major cause of pancreatitis in man, but this has not been reported in dogs, presumably because of the low prevalence of biliary stones in this species and because dogs have an accessory pancreatic duct that does not communicate with the common bile duct and serves as the main pancreatic duct.[10] Congenital anomalies of the pancreatic duct system may predispose to pancreatitis in man, and similar mechanisms may occur in the dog but have not been documented.

Reflux of duodenal juice into the pancreatic ducts secondary to surgical creation of a closed duodenal loop causes severe acute pancreatitis. Under normal circumstances such reflux is unlikely to occur because the duct opening is surrounded by a specialized compact smooth mucosa over the duodenal papilla and is equipped

with an independent sphincter muscle; however, this antireflux mechanism may sometimes fail owing to an abnormally high duodenal pressure, such as may occur during vomiting or after blunt trauma to the abdominal cavity.

Surgical manipulation and blunt abdominal trauma are also potential causes of pancreatitis, but reports of pancreatitis after such insults are rare.[2] Pancreatitis after pancreatic biopsy is extremely rare, and is also uncommon after resection of pancreatic neoplasms.[2]

Experimental and clinical reports have indicated that ischemia is important in the pathogenesis of acute pancreatitis, either as a primary cause or as an exacerbating influence. Pancreatic ischemia may develop during shock, secondary to hypotension during general anesthesia, or during temporary occlusion of venous outflow during surgical manipulation in the anterior abdomen. In some cases this may explain some instances of postoperative pancreatitis when areas remote from the pancreas have undergone surgery.

Viral, mycoplasmal, and parasitic infections may be associated with pancreatitis, although this is usually recognized as part of a more generalized disease process.[2] Recently, pancreatitis has been recognized as a potential complication of babesiosis.[11] It is unknown whether bacterial infection plays a role in the development of pancreatitis in some cases, but concomitant bacterial infection does increase the severity of experimental pancreatitis.[2] Pancreatitis may occur in association with end-stage renal failure, but this is rare. It is likely that renal failure secondary to acute pancreatitis is encountered more frequently.[2] Finally, autoimmune mechanisms have been incriminated in a small subset of human patients with pancreatic inflammation that responds to glucocorticoid therapy.[12]

232.2 DIAGNOSIS

232.2.1 History and Clinical Signs

Although dogs of any age and body condition may develop pancreatitis, affected animals are usually middle aged or older and are often overweight. Dogs with acute pancreatitis are usually presented because of vomiting, weakness, abdominal pain, depression, or diarrhea.[13] Severe acute disease may be associated with shock and collapse. Some dogs demonstrate abdominal pain by assuming a “prayer” position, with the forelimbs stretched out, the sternum on the ground, and the hindlimbs raised. Signs of pain may also be elicited by abdominal palpation, although some animals do not react even though they have severe acute pancreatitis. Abdominal pain is the most consistent clinical sign in human patients, being reported in more than 90% of cases. By comparison a study in dogs reported abdominal pain in only 59% of cases.[13] This probably reflects failure to detect abdominal pain rather than its absence. An anterior abdominal mass is palpable in some cases, and occasionally mild ascites occur. Dogs with severe disease are often dehydrated and may be febrile. Uncommon systemic complications of pancreatitis that may be apparent on physical examination include jaundice, respiratory distress, bleeding disorders, and cardiac arrhythmias.[2] In some patients the onset of signs may have followed ingestion of a large amount of fatty food.[13]

1484 1485

The clinical signs of mild, acute, and chronic pancreatitis in dogs are poorly documented but are probably extremely variable and nonspecific. The disease may not be clinically apparent at all. As a consequence, mild disease remains undiagnosed in the vast majority of cases.

232.2.2 Diagnostic Imaging

Radiographic findings in dogs with pancreatitis include an increased density, diminished contrast (*ground glass* appearance), and granularity in the right cranial abdomen, displacement of the stomach to the left, widening of the angle between the pyloric antrum and the proximal duodenum, displacement of the descending duodenum to the right, presence of a mass medial to the descending duodenum, static gas pattern in or thickened walls of the descending duodenum, static gas pattern in or caudal displacement of the transverse colon, gastric distension suggestive of gastric outlet obstruction, and delayed passage of barium through the stomach and duodenum with corrugation of the duodenal wall. Unfortunately these findings are subjective, and definitive radiographic evidence of pancreatitis is usually not present. However, abdominal radiographs may provide evidence to rule in or rule out alternative diagnoses.

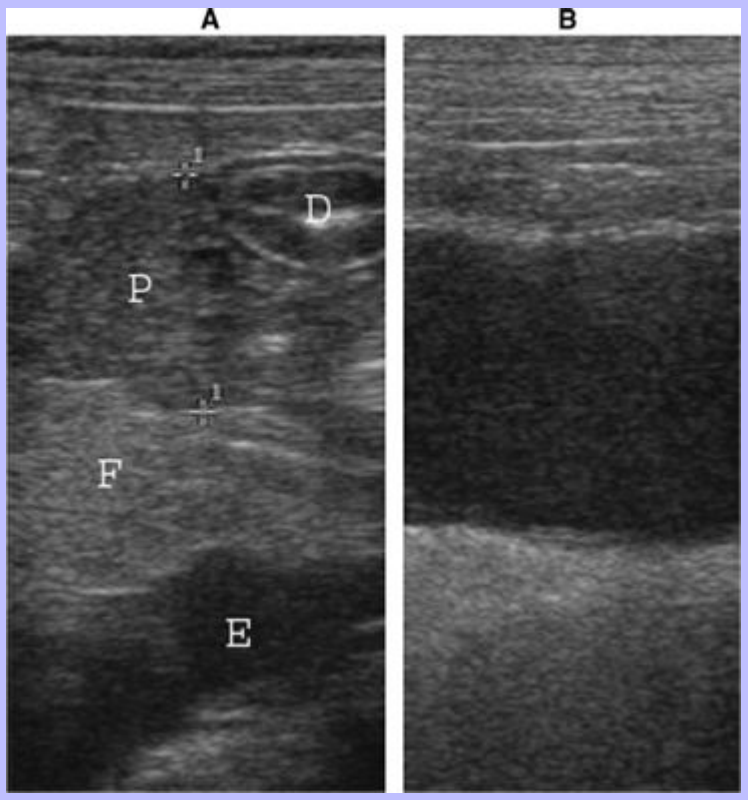
Abdominal ultrasonography is highly specific for pancreatitis when stringent criteria are applied, with a sensitivity of up to approximately 70% in dogs and 30% in cats.[13] Enlargement of the gland, localized peritoneal effusion, or both are not sufficient for a diagnosis. Changes in echogenicity are quite useful. A decrease in echogenicity indicates pancreatic necrosis, which is often associated with hyperechogenicity in the peripancreatic region (Figure 232-2). Hyperechogenicity of the pancreatic parenchyma itself indicates pancreatic fibrosis and can be seen in cases of chronic pancreatitis. Pancreatic duct dilation also has been reported in cats.[2,3] Serial examinations are particularly useful for identification and management of pancreatic complications such as pancreatic pseudocyst or abscess.

Computed tomography (CT) is the most useful modality for visualizing the pancreas and for identifying pancreatic necrosis in human patients, but financial considerations and the much smaller size of the pancreas will likely limit its usefulness in the dog.

232.2.3 Clinical Pathology

Leukocytosis, often associated with a left shift, is a common hematologic finding in acute pancreatitis. The packed cell volume (PCV) may be increased as a result of dehydration, but anemia is also frequently observed.[2,3,13] Azotemia is often present, usually reflecting dehydration, but it may also reflect secondary acute renal failure.[14] Activities of hepatic enzymes are often increased, reflecting either hepatic ischemia or exposure of the liver to high concentrations of toxic products from the pancreas.[2,15] Hyperbilirubinemia and clinically apparent icterus may occur, possibly indicating severe hepatocellular damage, intrahepatic and extrahepatic obstruction of bile flow, or both. Hyperglycemia is common as a result of hyperglucagonemia, stress-related increases in the concentrations of catecholamines and cortisol, or destruction of islet cells by pancreatic inflammation. Some dogs remain diabetic after recovery from acute episodes of pancreatitis.[2] Hypocalcemia has often been reported, usually secondary to hypoalbuminemia but is usually mild to moderate and rarely associated with clinical signs of tetany.[2,3] Hypocalcemia can also be due to deposition of calcium as soaps after excessive generation of fatty acids by the breakdown of fat. Hypercholesterolemia and hypertriglyceridemia are common, and hyperlipemia is often grossly apparent even though food has not been ingested recently. Hyperlipidemia may prevent accurate determination of some serum biochemical values.[2]

Figure 232-2 Ultrasonographic scans of the cranial abdomen in two dogs. The dog in panel **A** had severe pancreatitis. The duodenum can be seen in the upper right hand corner (*D*). The pancreas can be seen as an irregular mixed echoic structure (*P*). The dark areas within the pancreas represent areas of pancreatic necrosis. The hyperechoic area right below the mixed echoic structure represents peripancreatic fat necrosis (*F*). The hypoechoic area below the peripancreatic fat suggests peritoneal effusion (*E*). The changes seen here are highly specific for acute pancreatitis. The dog shown in panel **B** had a pancreatic abscess. A large uniformly hypoechoic structure exists that suggests a fluid-filled mass. Such a fluid-filled mass could represent a pancreatic pseudocyst or a pancreatic abscess and was diagnosed as a pancreatic abscess in this patient. (Images courtesy of Dr. Sharon Shull.)



Assays for several pancreatic enzymes and zymogens in serum have been evaluated for the diagnosis of canine pancreatitis, including amylase and lipase activities, serum trypsin-like immunoreactivity (cTLI), pancreatic

lipase immunoreactivity (cPLI), trypsin-α_1-proteinase inhibitor complexes, and serum and urinary trypsinogen activation peptide (TAP).[2,3,16]

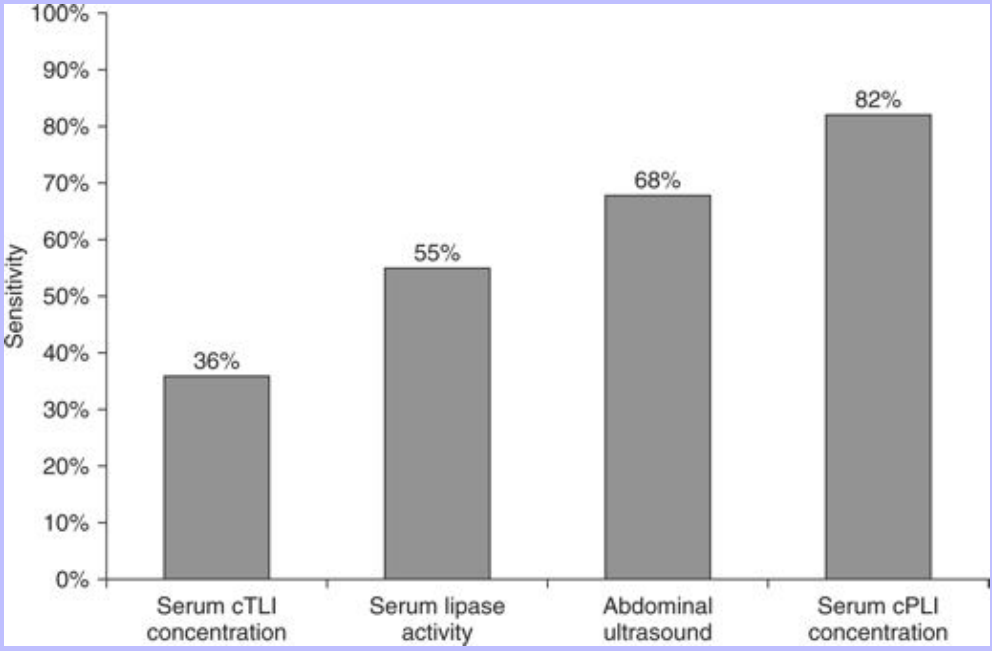
Serum amylase and lipase activities have been used to diagnose canine pancreatitis for several decades, but both have been repeatedly shown to lack sensitivity and specificity.[10] In general, approximately 50% of patients with an elevated serum amylase activity, lipase activity, or both do not have pancreatitis. Trypsin complexed with plasma α_1-proteinase inhibitor and TAP in plasma or urine should act as specific markers for pancreatitis.[16] However, a recent study found urinary TAP concentration to be very insensitive even though it was highly specific.[16] Plasma TAP concentration was slightly more sensitive but also had a lower specificity of 77%.[16] Taking into consideration the cost of the assay, the limited availability of laboratories providing the assay, and the lack of stability of TAP, this assay is of little clinical usefulness for the diagnosis of canine pancreatitis. A recently developed assay for serum trypsin-α_1-proteinase inhibitor complex concentrations did not prove to be useful for the diagnosis of spontaneous pancreatitis in the dog. Serum cTLI concentration is specific for exocrine pancreatic function and is the test of choice for EPI, but its short half life renders it fairly insensitive for the diagnosis of canine pancreatitis.

1485
1486

Serum cPLI concentration is highly specific for exocrine pancreatic function and appears to be a useful marker for pancreatic inflammation. In a recent study of 11 dogs with biopsy-confirmed pancreatitis, all 11 dogs had serum cPLI concentrations above the upper limit of the reference range, and nine of 11 dogs (82%) had concentrations above a cutoff value of 200 µg/L.[18] Serum cPLI is not elevated in dogs with gastritis and experimentally induced chronic renal failure; it is also not affected by administration of prednisone. Thus serum cPLI is the most sensitive (Figure 232-3) and specific diagnostic test for canine pancreatitis currently available.

Pancreatic biopsy obtained by exploratory laparotomy or laparoscopy is often considered the gold standard for diagnosing canine pancreatitis, but it has limitations. In a recent study, less than 10% of dogs with pancreatitis showed gross anatomic evidence of pancreatitis. In addition, histologic examination often reveals the distribution of pancreatitis to be patchy and highly localized. Thus although the presence of pancreatic inflammation, necrosis, or both can be considered definitive evidence for pancreatitis, a lack of such findings (even if multiple biopsies are evaluated) does not definitively exclude pancreatitis. Moreover, the risk of anesthesia may be elevated in patients with pancreatitis, making the collection of a biopsy potentially detrimental in such cases.

Figure 232-3 This figure shows a comparison of the sensitivity for different diagnostic modalities for a diagnosis of canine pancreatitis. The reader should note that serum cTLI concentration, abdominal ultrasound, and serum cPLI concentration have a high specificity for canine pancreatitis, whereas only approximately 50% of dogs with an elevated serum lipase activity have pancreatitis.[13,18]



232.3 TREATMENT

The classic therapy for acute pancreatitis is maintenance of fluid and electrolyte balance while the pancreas is "rested" by withholding food.[2] Recent reports have challenged the logic and wisdom of withholding food, however, and both parenteral and enteral nutrition have been well tolerated by patients with pancreatitis.[19] Evidence also indicates that enteral nutrition may be superior to parenteral nutrition. Oral intake should probably be restricted only in those patients with incessant vomiting, and then for as short a period as possible.

If drug-induced pancreatitis is suspected, any incriminated agents should be withdrawn and replaced by an unrelated alternative drug, if necessary. Other potential causative factors (see previous discussion) should similarly be investigated and, if possible, eliminated. Balanced electrolyte solution should be given intravenously to replace fluid deficits and provide maintenance requirements. Mild cases of pancreatitis are probably self-limiting and may improve without therapy. Other patients require aggressive fluid therapy over several days to treat severe dehydration and ongoing fluid and electrolyte loss due to vomiting. Many animals become hypokalemic during such therapy, and serum potassium should be monitored and supplemented parenterally if required. Serum creatinine and blood urea nitrogen (BUN) should also be monitored to document resolution of

azotemia, thereby ruling out associated renal failure. Although metabolic acidosis is probably common in acute pancreatitis, this may not always be the case, and vomiting patients may be alkalotic. Therefore blind correction of suspected acid-base abnormalities should not be attempted.[2] It is common practice to administer antibiotics to dogs with pancreatitis, particularly when toxic changes are evident on the hemogram or when the patient is febrile. Antibiotic therapy appears to be beneficial in human patients and in some experimental models of pancreatitis; in contrast to humans, dogs with pancreatitis rarely have infectious complications, and antibiotic therapy would appear to be of minimal benefit. However, for cases where good evidence for pancreatic infection exists, it should be noted that trimethoprim sulfa and enrofloxacin penetrate well into the exocrine pancreas in dogs.

1486

1487

Analgesic therapy (subcutaneous meperidine hydrochloride, transdermal fentanyl, morphine by constant rate intravenous infusion, or intraperitoneal lidocaine) should be given to provide relief of pain, even if obvious signs of pain are not apparent.[20] Hyperglycemia is often mild and transient, but in some cases diabetes mellitus may develop, requiring treatment with insulin. Respiratory distress, neurologic problems, cardiovascular abnormalities, bleeding disorders, and acute renal failure are all poor prognostic indicators. Attempts should be made to manage these complications by appropriate supportive measures.

Some affected animals do not improve or continue to deteriorate in spite of intensive supportive care. Evidence indicates that, in severe pancreatitis, marked consumption of plasma protease inhibitors occurs and that saturation of available α-macroglobulins is rapidly followed by acute DIC, shock, and death.[21] Transfusion of plasma or whole blood to replace α-macroglobulins may be life saving in these circumstances, and it has the additional benefit of maintaining plasma albumin concentrations.[22] Low-molecular-weight dextrans have also been used to expand plasma volume, but they may aggravate bleeding tendencies, contain no protease inhibitor, and provide no major advantages over plasma administration. The use of corticosteroids in pancreatitis has been recommended by some because they stabilize lysosomal membranes, reduce inflammation, and alleviate shock, but they have not been shown to be of value in experimental studies.[2] Unless autoimmune pancreatitis is suspected, they should be given only on a short-term basis to animals in shock. Attempts to rest the pancreas by use of direct inhibitors of secretion such as atropine, acetazolamide, glucagon, calcitonin, and somatostatin or its analogues have not proved effective. Recent data have suggested that somatostatin may even have detrimental effects in experimental pancreatitis, and its use cannot be recommended. Administration of a variety of naturally occurring and synthetic enzyme inhibitors with selective actions against individual pancreatic digestive enzymes has shown promise in experimental studies, but these agents have not been shown to be beneficial in human patients with pancreatitis. Inhibition of gastric secretion by use of antacids or cimetidine and suctioning off gastric secretions have been used in an attempt to inhibit pancreatic secretion, however, none of these methods has been consistently shown to be effective. In one study the use of sodium selenite as an antioxidant was reported to lead to a significant decrease in mortality in dogs with pancreatitis. This study was not controlled, and controlled studies in human patients with pancreatitis failed to show any clinical benefit. The use of peritoneal dialysis to remove toxic material accumulated in the peritoneal cavity is believed by some to be useful in human patients with pancreatitis, but it has not been shown reproductivity to be useful and is rather impractical in canine patients with pancreatitis. In some cases pancreatitis may be localized to one lobe of the gland, and surgical resection of the affected area may be followed by complete recovery. Future clinical and experimental trials will probably be directed at the use of agents to modify events currently believed to be important in the pathogenesis of pancreatitis, including inhibitors of inflammatory mediators, free-radical scavengers, enzyme synthesis and transport inhibitors, and factors that may stabilize lysosomal and other cell compartment membranes.[5]

After vomiting has subsided, small amounts of water should be offered; if no exacerbation of clinical signs occurs, food may be gradually reintroduced. The diet should preferably have a high carbohydrate content (rice,

pasta, potatoes) because protein and fat are more potent stimulants of pancreatic secretion and are perhaps more likely to promote a relapse. If improvement continues, gradual introduction of a low-fat maintenance diet should be attempted.[19]

In many patients with a single episode of pancreatitis, the only long-term therapy recommended is to avoid feeding high-fat meals. In patients with repeated bouts of pancreatitis occur, and it may be beneficial to feed a fat-restricted diet permanently. In some patients, hypertriglyceridemia may need to be controlled pharmacologically. Despite all efforts, some animals experience recurrent disease.[23]

Some reports have indicated that oral pancreatic enzyme supplements decrease abdominal pain and discomfort that accompanies chronic pancreatitis in humans. It is unknown whether they are of similar value in dogs, but a trial period of enzyme therapy may be warranted in dogs with chronic signs of abdominal pain or anorexia.

232.4 PROGNOSIS

Pancreatitis is an unpredictable disease of widely varying severity, and it is difficult to give a prognosis. Life-threatening signs accompanying acute fulminating pancreatitis are usually followed by death in spite of supportive measures, but some dogs recover fully after an isolated severe episode. In other cases relatively mild or moderate chronic or recurrent pancreatitis persists despite all therapy, and the patient either dies during an acute severe exacerbation of the disease or undergoes euthanasia because of failure to recover and the expense of long-term supportive care. Most patients with uncomplicated pancreatitis probably recover spontaneously and do well as long as high-fat diets are avoided.

232.5 PANCREATIC PSEUDOCYST

A pancreatic pseudocyst is a collection of sterile pancreatic juice, enclosed by a wall of fibrous or granulation tissue and occurs as a complication of pancreatitis.[1] Recently, several cases of pancreatic pseudocysts in dogs have been described.[24] Clinical signs are usually nonspecific and mimic those of pancreatitis. On abdominal ultrasound a cystic structure in close proximity to the pancreas can be identified. Aspiration of the pseudocyst is relatively safe and should be attempted for diagnostic and therapeutic purposes.[24] In contrast to fluid from a pancreatic abscess, the drained fluid from a pancreatic pseudocyst should be of low cellularity and should not contain any evidence of inflammation. Pancreatic pseudocysts can be treated medically or surgically. Surgical correction can involve extirpation of the pseudocyst, external drainage, or internal drainage, but internal drainage is the preferred treatment in human patients. Medical management of pancreatic pseudocysts involves ultrasound-guided percutaneous aspiration and close monitoring of the size of the pseudocyst. This approach was successful in several cases described in the human medical literature.[24] However, surgical intervention should be considered in cases in which clinical signs persist or when the size of the pseudocyst does not decrease significantly over time.

232.6 PANCREATIC ABSCESS

A pancreatic abscess is another possible complication of pancreatitis.[1] A pancreatic abscess is a circumscribed collection of pus, usually in proximity to the pancreas, containing little or no pancreatic necrosis.[1] In dogs, bacterial infection is only rarely present.[25,26] Clinical signs are nonspecific, but may include vomiting, depression, abdominal pain, anorexia, fever, diarrhea, and dehydration. In some patients a mass in the cranial

abdomen can be identified upon abdominal palpation.[25] Common clinicopathologic findings are neutrophilia with a left shift, elevation of serum amylase and lipase activities, elevations of hepatic enzyme activities, and hyperbilirubinemia.[25,26] Surgical drainage and aggressive antimicrobial therapy are the treatment of choice in human patients with pancreatic abscess. Dogs may also respond favorably to surgical drainage.[25] However, in one report only five of nine patients survived the immediate postsurgical period.[26] Thus given the mixed results, risks, difficulties, and expenses associated with anesthesia, surgery, and postoperative care, one may want to avoid surgical intervention unless clear evidence exists of an enlarging mass, sepsis, or both in a patient that is not responding well to medical therapy. Antimicrobial therapy in dogs is of questionable value unless an organism is identified upon bacterial culture.

1488

232.7 EXOCRINE PANCREATIC NEOPLASIA

Pancreatic adenomas are benign tumors that are usually singular and can be differentiated from pancreatic nodular hyperplasia by the presence of a capsule. Pancreatic adenocarcinoma is the most common neoplastic condition of the exocrine pancreas in the dog; however, in contrast to humans, where pancreatic adenocarcinoma is the fifth most com-mon malignancy, it occurs rather infrequently in dogs. Adenocarcinomas usually originate from the duct system but can also originate from acinar tissue. A few cases of pancreatic sarcomas (i.e., spindle cell sarcoma, lymphosarcoma) have been reported. Whether these tumors are primary neoplastic lesions of the exocrine pancreas, metastatic lesions of tumors of other organs, or a localized lesion of a multicentric neoplasia is open to question.

232.7.1 Cause and Pathogenesis

The cause of neoplastic conditions of the exocrine pancreas is unknown. Benign neoplastic lesions can lead to transposition of cranial abdominal organs. However, these changes are subclinical in most cases, and the diagnosis is often made as an incidental finding at necropsy examination. In very few cases a benign growth can obstruct the pancreatic duct and cause secondary atrophy of the remaining exocrine pancreas leading to EPI. Adenocarcinomas can also cause transposition of cranial abdominal organs and obstruction of the pancreatic duct. In addition, adenocarcinomas can be associated with tumor necrosis and resulting pancreatic inflammation when the tumor outgrows its vascular supply. Pancreatic adenocarcinomas can also spread to neighboring or distant organs.

232.7.2 Clinical Signs and Diagnosis

The presentation of canine patients with exocrine pancreatic neoplasia is nonspecific, and clinical signs observed are often those of chronic pancreatitis such as vomiting, anorexia, diarrhea, or chronic weight loss. Multifocal necrotizing steatitis has been described in a few dogs that were ultimately diagnosed with pancreatic adenocarcinoma. Clinical signs related to metastatic lesions, such as lameness, bone pain, or dyspnea, have also been reported in some cases of pancreatic adenocarcinoma.

Neutrophilia, anemia, hypokalemia, bilirubinemia, azotemia, hyperglycemia, and elevations of hepatic enzymes have all been reported in affected patients, but results of routine blood tests may be unremarkable. Elevations of hepatic enzymes and serum bilirubin concentration are identified most commonly.[27] Hyperglycemia, when present, is related to concurrent destruction of pancreatic beta cells. Some dogs with pancreatic adenocarcinoma have extremely high serum lipase activities that reach values that are as high as 25

times the upper limit of the reference range. A single dog with a pancreatic adenocarcinoma and pseudohyperparathyroidism, leading to hypercalcemia, has been described in the literature.

Radiographic findings are also nonspecific in most cases. Abnormal findings include decreased contrast in the cranial abdomen, suggesting peritoneal effusion into this area, transposition of the spleen caudally, and shadowing in the pyloric region. In some cases abdominal radiographs can suggest the presence of a mass in the cranial abdomen.[27] In most cases a soft tissue mass can be identified by abdominal ultrasonography in the region of the pancreas.[27,28] However, in many if not most cases, the pancreatic origin of the mass cannot be conclusively established.[27] Similarly, neoplastic lesions of neighboring organs may be falsely presumed to be of pancreatic origin. In addition, patients with severe pancreatitis may show an ultrasonographic mass effect in the area of the pancreas that must not be confused with a pancreatic adenocarcinoma. If peritoneal effusion is identified on abdominal ultrasound, a sample should be aspirated and evaluated cytologically, but in most cases carcinoma cells do not readily exfoliate into the peritoneal effusion, and neoplastic cells are not routinely identified on cytology. Fine needle aspiration or transcutaneous biopsy under ultrasound guidance can be attempted when suspicious masses are identified and has been reported to be successful in approximately 25% of all cases.[27] The low success rate of fine needle aspiration is probably due to the lack of exfoliation of pancreatic adenocarcinoma cells. In other cases carcinoma cells can be identified, but the origin of the cells cannot be determined conclusively.[27] Ultrasound-guided biopsy with histopathologic evaluation of biopsies has been reported infrequently; however, in one study ultrasound-guided biopsy of a pancreatic mass resulted in a diagnosis of pancreatic adenocarcinoma in two of two cases.[27] In two of three more cases, biopsy of the liver revealed metastatic carcinoma.[27] In many cases the diagnosis is made at exploratory laparotomy or even on necropsy examination.

232.7.3 Therapy and Prognosis

Pancreatic adenomas are benign and theoretically do not need to be treated unless they cause clinical signs. However, because the definitive diagnosis of pancreatic adenocarcinoma is often made by histopathology, a partial pancreatectomy should be performed even in cases of suspected pancreatic adenoma. The prognosis in these cases is excellent. Pancreatic adenocarcinomas often present at a late stage of the disease. In human patients with pancreatic adenocarcinoma, metastatic disease is usually present at the time of diagnosis; this is also common in dogs with this disease. The most common sites of metastatic disease are the liver, abdominal and thoracic lymph nodes, mesentery, intestines, and the lungs, but various other metastatic sites have also been reported.[27] In those few cases when gross metastatic lesions are not identified at the time of diagnosis, surgical resection of the tumor may be attempted, but owners should be forewarned that clean surgical margins are only rarely achieved. Total pancreatectomy and pancreaticoduodenectomy, though theoretically possible, have not been described in dogs with spontaneous disease. Extrapolation from human patients suggest high morbidity and mortality for these procedures.[29] To this point, chemotherapy or radiation therapy have shown little success in human or veterinary patients with pancreatic adenocarcinomas. Overall, the prognosis for dogs and cats with pancreatic adenocarcinoma is grave.

232.8 NODULAR HYPERPLASIA

Nodular pancreatic hyperplasia occurs quite frequently in older dogs.[10] Disseminated small nodules can be found throughout the pancreas and can be differentiated from pancreatic adenomas by the absence of a capsule.[10]

Nodular hyperplasia does not lead to functional changes or clinical signs and is thus most frequently diagnosed incidentally during necropsy of older dogs.

233 CHAPTER • 233 Feline Exocrine Pancreatic Disease

Jörg M. Steiner

David A. Williams

Diseases of the exocrine pancreas, once believed to be rare in cats, are now known to occur frequently in this species. Pancreatitis is the most common disorder, followed by exocrine pancreatic neoplasia, exocrine pancreatic insufficiency (see Chapter 234), and other miscellaneous conditions.

233.1 PANCREATITIS

The overall prevalence of feline pancreatitis is unknown but as the diagnostic accuracy for this disease is improving, this disease is being diagnosed with increasing frequency. The classification of feline pancreatitis is analogous to the dog (see Chapter 232), but in contrast to dogs, cats are more likely to have chronic disease.

Pancreatitis is ultimately due to autodigestion of the exocrine pancreas by prematurely activated digestive enzymes, most importantly proteases and phospholipases. Pathogenetic mechanisms that initiate clinical disease are the same as in the dog, as are the protective mechanisms that normally protect the pancreas from autodigestion (see Chapter 232).

233.1.1 Etiology

The majority of feline pancreatitis cases are idiopathic; however, a number of causes and risk factors have been identified. A cause-and-effect relationship has been established for *Toxoplasma gondii* and the hepatic fluke *Amphimerus pseudofelineus* (see below), but other infectious organisms, such as panleukopenia and feline infectious peritonitis, have also been implicated. Blunt trauma to the abdominal cavity such as seen in cats that have been hit by car or fallen from great heights (“high-rise syndrome”) can cause pancreatitis, as can surgical manipulation and ischemia secondary to hypotension during anesthesia.

Drugs are an important cause of pancreatitis in human patients and a variety of drugs have been implicated in causing pancreatitis in human beings. However, a cause-and-effect relationship, although likely, has yet to be confirmed in cats. Pancreatitis due to organophosphate intoxication has been documented in cats.[1] The role of inflammatory diseases of the liver and the intestines in the pathogenesis of feline pancreatitis is unknown, but many cats with chronic pancreatitis also have inflammatory infiltrates of these organs. Indeed, diagnosis of chronic pancreatitis in cats should prompt diagnostic evaluation for potential concurrent inflammatory bowel disease (IBD), and vice versa.

233.1.2 Diagnosis

233.1.2.1 History and Clinical Signs

The history of cats with pancreatitis is extremely variable. Most cats with severe disease present with a history of lethargy and anorexia.[1] Key clinical signs of acute pancreatitis in dogs and human beings, vomiting and abdominal pain, have been reported in only 35% and 25%, respectively, of cats with severe

pancreatitis.[1] Hypothermia, dyspnea, diarrhea, and ataxia have also been reported.[1] Mild chronic pancreatitis may be subclinical or may cause anorexia and weight loss.

233.1.2.2 Diagnostic Imaging

Abdominal radiographs are only of limited usefulness for the diagnosis of pancreatitis. Possible findings are the same as in dogs and are also nonspecific in cats (see previous chapter). Thoracic radiographs may show pleural effusion in severe cases. Abdominal ultrasound is highly specific for feline pancreatitis if stringent criteria are applied. Again, findings are the same as in the dog (see Figure 232-2), but additionally pancreatic duct dilation has been reported during abdominal ultrasound examination.[2,3] Although highly specific for feline pancreatitis the sensitivity of abdominal ultrasound for pancreatitis has been reported to be only 10% to 35% when performed by a board-certified ultrasonographer.[4] A recent report assessing the clinical usefulness of contrast-enhanced computed tomography in cats with pancreatitis found this diagnostic modality to be even less sensitive than abdominal ultrasonography.[4]

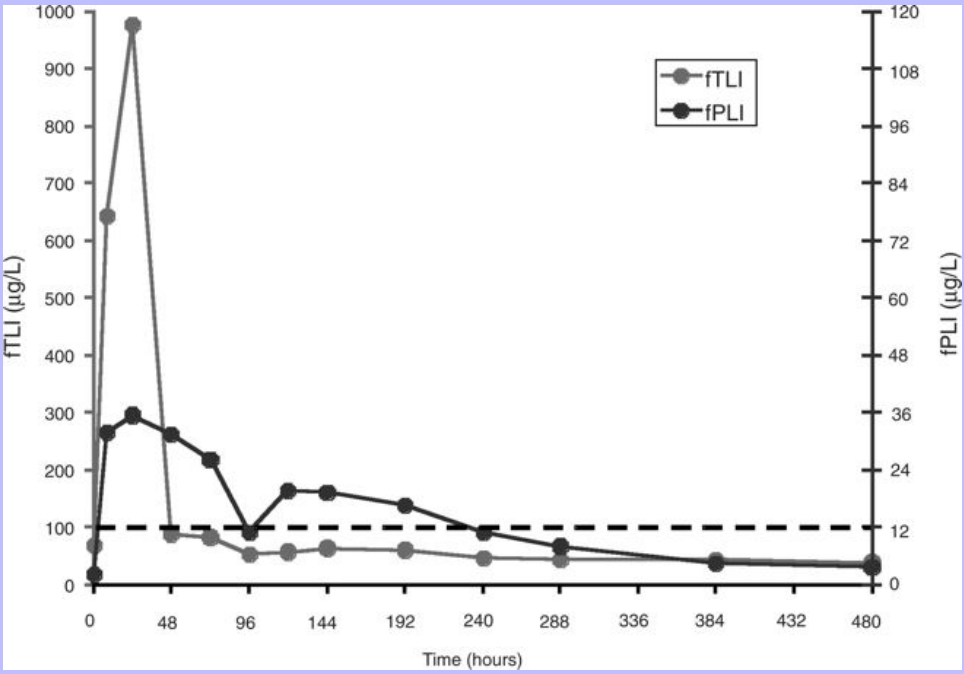
233.1.2.3 Clinical Pathology

Changes in the complete blood count and serum chemistry profile are often mild and nonspecific.[1] Elevations of liver enzymes are common in severe cases and indicate secondary hepatic lipidosis or concurrent cholangitis or cholangiohepatitis.[5,6]

Serum lipase activity increases and serum amylase activity decreases in feline experimental pancreatitis.[7] However, the only study that evaluates the clinical utility of these serum enzyme activities in cats with spontaneous disease found no difference in the mean or the ranges of serum lipase or amylase activities between 12 cats with severe pancreatitis, 43 normal cats, and 31 cats with other diseases. These results suggest that these tests are of no value in the diagnosis of feline pancreatitis.[8] Serum feline trypsin-like immunoreactivity (fTLI) concentration is specific for exocrine pancreatic function in the absence of azotemia, but depending on the study the sensitivity of this diagnostic test for feline pancreatitis ranges between 30% and 60%.

An assay for serum feline pancreatic lipase immunoreactivity (fPLI) has recently been developed and initial clinical studies have been promising. In a group of cats with experimentally induced pancreatitis, both serum fTLI and fPLI concentrations increased initially, but serum fPLI concentration stayed elevated much longer than did serum fTLI concentration (Figure 233-1).[9] Another study of cats with spontaneous pancreatitis showed serum fPLI concentration to be both more sensitive and more specific for diagnosing pancreatitis than serum fTLI concentration or abdominal ultrasonography.[10] At the time of writing both the fTLI and the fPLI assay are performed only at the authors' laboratory.[*]

Figure 233-1 Mean serum fTLI and fPLI concentrations over time in six cats with experimentally induced pancreatitis. The gray line shows the mean serum fTLI concentrations over time and the black line shows the mean serum fPLI concentrations. The broken line displays the currently recommended cut-off value for the diagnosis of pancreatitis for serum fTLI concentration of 100 µg/L and that for serum fPLI concentration of 12 µg/L. The elevation of mean serum fPLI concentration is of far greater duration than that of mean serum fTLI concentration. These data indicate that serum fPLI concentration is more sensitive than serum fTLI concentration for the diagnosis of feline pancreatitis.[9]



Traditionally, histopathology of a pancreatic biopsy has been considered the gold standard for diagnosis of feline pancreatitis. However, gross anatomic lesions are not consistently seen and pancreatic inflammation is often localized to a small area of the gland in both acute and chronic pancreatitis. Furthermore, although pancreatic biopsy per se is safe, it is expensive and may be contraindicated in patients at risk for anesthetic complications.

233.1.3 Treatment

233.1.3.1 Treatment of Severe Pancreatitis

For the most part treatment of severe pancreatitis mirrors that of dogs (see previous chapter). However, special consideration must be given to nutritional support as most cats with pancreatitis present with a history of anorexia and hepatic lipidosis is common in these patients.[6] Cats that do not vomit should be offered a low-fat diet orally. If the cat is anorectic, as most cats will be, a nasogastric, esophageal, or gastrostomy tube is the most practical route of alimentation. If these routes are contraindicated a jejunostomy tube should be placed. Partial or total parenteral nutrition are other alternatives but a jejunostomy tube is preferable.

Abdominal pain is infrequently recognized in cats with pancreatitis but probably occurs in most patients. In many patients previous abdominal pain becomes apparent after analgesia has been instituted and thus analgesic therapy is indicated in all patients.

233.1.3.2 Mild Pancreatitis

As stated earlier, cats with mild pancreatitis often have evidence of concurrent inflammatory bowel disease and or cholangiohepatitis. Although corticosteroids are believed to be of no benefit in most patients with acute pancreatitis, the authors' experience indicates that corticosteroids can be safely used in cats with concurrent chronic pancreatitis and inflammatory bowel disease. Indeed, successful treatment of IBD with prednisolone appears to lessen the severity of pancreatitis in some of these cats. Cats with concurrent IBD often have subnormal serum cobalamin concentrations, and cobalamin supplementation is essential for optimal therapeutic response in these cases. Cats with mild pancreatitis also may benefit from a low fat diet, although the potential benefit of such diets is not as clear as in dogs. The use of exogenous pancreatic enzymes is commonly recommended in human beings with abdominal pain due to chronic pancreatitis. Exogenous pancreatic enzymes inhibit pancreatic enzyme secretion by a negative feedback mechanism in both dogs and human beings, and this may ameliorate pain in chronic pancreatitis. Although no data are available for cats, trial therapy with pancreatic enzymes should be considered in cats that show either abdominal pain or anorexia attributable to abdominal pain.

1490 1491

The true prevalence of the hepatic fluke *Amphimerus pseudofelineus* in cats is unknown and infestation is usually missed during routine fecal examination. Thus, empiric treatment with praziquantel (see below) may be warranted in cats with chronic pancreatitis.

233.1.4 Prognosis

The prognosis for cats with pancreatitis is directly related to the severity of the disease, the extent of pancreatic necrosis, the occurrence of systemic and pancreatic complications, the duration of the condition, and to the presence of concurrent disease. In a recent report a plasma ionized calcium concentration below 1.00 mmol/L in cats with pancreatitis was a poor prognostic indicator associated with 77% mortality.[11]

As previously mentioned, common concurrent conditions in cats with pancreatitis include hepatic lipidosis, cholangiohepatitis, enteritis, diabetes mellitus, and interstitial nephritis, all of which may negatively influence

the overall prognosis of the patient.[12] However, most cats with IBD and concurrent pancreatitis respond well to treatment of IBD.

233.2 PANCREATIC PSEUDOCYST

A pancreatic pseudocyst is a common complication of pancreatitis in human beings but has been reported in only one cat to date.[13,14] The clinical signs observed in the cat described were nonspecific and similar to those seen in some cats with pancreatitis. A mass was palpated in the cranial abdomen and a cystic structure in close proximity to the left lobe of the pancreas was identified on abdominal ultrasonography.[13] Surgical correction is the treatment of choice for pancreatic pseudocysts in human beings in cases when they enlarge or do not regress. Surgical correction was also successfully employed in the management of the cat reported.[13]

233.3 PANCREATIC ABSCESS

A pancreatic abscess is another common complication of pancreatitis in human beings.[14] A pancreatic abscess is a circumscribed collection of pus, usually in proximity to the pancreas, and contains little or no pancreatic necrosis.[14] To date a pancreatic abscess in a cat has not been described.

233.4 EXOCRINE PANCREATIC NEOPLASIA

Pancreatic adenocarcinomas, adenomas, or other primary or metastatic neoplastic lesions have been reported in cats.[15,16] Adenocarcinomas are the most common neoplasia of the exocrine pancreas in cats. They are malignant and usually originate from the duct system but can also originate from acinar tissue.[15]

233.4.1 Etiology and Pathogenesis

Benign neoplastic lesions can lead to transposition of organs of the cranial abdomen, but these changes are subclinical in most cases and the diagnosis is often made as an incidental finding on necropsy examination. In some cases the pancreatic mass can obstruct the pancreatic duct and lead to pancreatic atrophy and clinical signs of exocrine pancreatic insufficiency or to pancreatic inflammation. Malignant neoplastic lesions can cause the same changes but can also be associated with tumor necrosis and pancreatitis. Malignant tumors can also spread to neighboring or distant organs.

233.4.2 Clinical Signs and Diagnosis

Cats with exocrine pancreatic neoplasia present with nonspecific clinical signs. In a report of 58 cases, clinical signs most commonly reported were anorexia (46%), weight loss (37%), lethargy (28%), vomiting (23%), icterus (14%), constipation (9%), and diarrhea (3%).[15] Clinical signs reported in other cases were polyuria, fever, dehydration, a distended cranial abdomen, and voluminous, pale, and soft stools.[16] Obstructive jaundice has also been described in a cat with pancreatic adenocarcinoma. Clinical signs due to metastatic lesions may also be observed and may include lameness, bone pain, or dyspnea. Recently several cases of paraneoplastic alopecia have been reported in cats with pancreatic adenocarcinoma.[17,18] The reported alopecia consisted of generalized alopecia of the ventrum, limbs, and face in most cases, and diffuse zones of alopecia in the remaining cats.[17,18]

Neutrophilia, anemia, hypokalemia, bilirubinemia, azotemia, hyperglycemia, and elevations of hepatic enzymes have all been reported in affected patients, but results of routine blood tests may be unremarkable.[15,16] Serum lipase and amylase activities may be elevated in isolated cases.

Radiographic and ultrasonographic findings in cats with exocrine pancreatic neoplasia are similar to those in dogs with this disease (see previous chapter). As in the dog cytologic evaluation of peritoneal effusion or of fine-needle aspirates are only useful in a small number of cases, but the low invasiveness and cost of these procedures warrant their use. In many cases pancreatic neoplasia is diagnosed at exploratory laparotomy or during necropsy examination.

233.4.3 Therapy and Prognosis

The considerations for treatment of exocrine pancreatic neoplasia in cats mirror those in dogs (see Chapter 232). Overall, the prognosis for cats with pancreatic adenocarcinoma is grave.

233.5 PANCREATIC PARASITES

Eurytrema procyonis, the pancreatic fluke of the cat, can be found in the pancreatic ductular system of foxes, raccoons, and cats. Little is known about the life cycle of this parasite. *Eurytrema procyonis* can lead to thickening of the pancreatic duct system and fibrosis. Even though a significant decrease of exocrine pancreatic secretion has been shown to occur in affected animals, cats presenting with clinical signs of EPI secondary to infestation with this parasite are extremely rare.[19] The diagnosis can be made by detection of characteristic dicrocoeliid eggs (average size 34 µm × 50 µm) with a single operculum in fresh feces during routine fecal floatation. Fenbendazole at a dose of 30 mg/kg per os once a day for 6 consecutive days has been recommended for therapy.[20]

The hepatic fluke of the cat, *Amphimerus pseudofelineus,* can also infest the pancreas and can lead to pancreatitis.[21] Infection with this parasite has been reported in cats from Illinois, Iowa, Louisiana, Maryland, Nebraska, Ohio, Texas, and Virginia.[21,22] The life cycle of this parasite is unknown, but it is presumed that similarly to other Opisthorchiidae, mollusces serve as first and freshwater fish as second intermediate host.[22] Diagnosis can be made on fecal examination by formalin-ethyl acetate sedimentation by identification of yellow-brown eggs of approximately 16 µm × 31 µm with a single operculum.[22] Eggs are destroyed during routine fecal floatation and infestation will be missed in those cases. In one report treatment with praziquantel at 40 mg/kg once daily for 3 consecutive days was successful in the management of *Amphimerus pseudofelineus* infestation.[22] Concurrent symptomatic therapy for pancreatitis, as outlined above, also needs to be instituted in these cases. The dose of praziquantel recommended is high when compared with the standard dose recommended for treatment of enteric parasites, but the therapeutic range for praziquantel is wide and the dose recommended is similar to that recommended for treatment of hepatic flukes in human beings.[22]

233.6 PANCREATIC BLADDER

A pancreatic bladder is an abnormal extension of the pancreatic duct. Pancreatic bladders can be congenital or acquired. Only a few cats with pancreatic bladders have been described in the literature. These patients were presented with clinical signs compatible with biliary duct obstruction. Appropriate management has not been studied, but surgical reconstruction may be of most benefit in cases presenting with clinical signs.

233.7 NODULAR HYPERPLASIA

As in older dogs, nodular pancreatic hyperplasia occurs quite frequently in older cats. Disseminated small nodules can be found throughout the exocrine portion of the pancreas. Pancreatic nodular hyperplasia can be differentiated from pancreatic adenomas by the absence of a capsule. Nodular hyperplasia does not lead to functional changes, does not cause any clinical signs, and is usually diagnosed incidentally during necropsy examination of older cats.

234 CHAPTER • 234 Exocrine Pancreatic Insufficiency in Dogs and Cats

Elias Westermarck

Maria Wiberg

Jörg M. Steiner

David A. Williams

234.1 CANINE EXOCRINE PANCREATIC INSUFFICIENCY

Chronic diseases of the exocrine pancreas may affect pancreatic function and lead to inadequate production of digestive enzymes, which causes maldigestion and then signs typical of exocrine pancreatic insufficiency (EPI). EPI is a functional diagnosis based on measurement of decreased pancreatic secretion capacity by pancreatic function tests. The exocrine pancreas has a large reserve secretory capacity and clinical signs of maldigestion do not occur until 90% of secretory capacity is lost. In dogs, underlying pathologic processes that may result in clinical signs of EPI are pancreatic acinar atrophy (PAA), chronic pancreatitis, pancreatic hypoplasia, and pancreatic neoplasia. Pancreatic acinar atrophy is reported to be by far the most common cause of severe EPI in dogs.[1,2]

234.1.1 Etiology

234.1.1.1 Pancreatic Acinar Atrophy

Pancreatic Acinar Atrophy (PAA) results from selective destruction of the digestive enzyme producing acinar cells, which may lead to almost complete loss of secretory capacity. The endocrine function of the pancreas usually is unaffected. PAA has been suggested to be a hypoplastic disease because of the young age of the affected dogs. However, general opinion has been that PAA is a progressive disease and it has been shown that the one dog that developed PAA later in life was born with grossly and histologically normal pancreas.[3]

Only a limited number of studies have been assessed the role of different environmental factors, nonmicrobial or microbial, in the development of PAA. In one study stress was suggested to be a possible triggering factor preceding the clinical disease.[4]

PAA has been reported in many breeds, but it is most common in German shepherd dogs and rough coated Collies. In both breeds, PAA has been suggested to be inherited.[5–7]

Recent studies in German shepherd dogs and rough-coated Collies have shown that PAA has features typical of autoimmune disease. With these two breeds it has been possible to diagnose the disease in a subclinical phase, before development of total acinar atrophy and the manifestation of clinical maldigestion signs.[8,9,10] Genetic susceptibility of the disease and the marked T-lymphocyte infiltration during the progression of acinar atrophy have been taken as primary evidence of autoimmune nature of the disease. The progression of acinar atrophy was divided into a subclinical phase, characterized by partial acinar atrophy and lymphocytic infiltration. The clinical phase is characterized by severe endstage atrophy. As

lymphocytic pancreatitis with active destruction of the acinar structures was shown to precede the end-stage atrophy, the term *autoimmune-mediated atrophic lymphocytic pancreatitis* is preferred to describe pathologic findings. Cellular immune mechanisms were shown to have a major role in the tissue destruction.[8–10]

234.1.1.2 Other Causes of EPI

Chronic pancreatitis is a common cause of EPI in cats and humans. It has been suggested as an underlying cause of EPI in older dogs, but its prevalence is still unclear. In chronic pancreatitis the clinical signs are usually those of nonspecific gastrointestinal disease. In this situation, the endocrine pancreas may also be affected. In chronic pancreatitis there can be a progressive destruction of both exocrine and endocrine pancreas, with fibrosis. Congenital exocrine or exocrine and endocrine pancreatic hypoplasia in young puppies is sometimes found. In conjunction with pancreatic neoplasia EPI is a rarely reported clinical sign.[1]

234.1.2 Diagnosis

Diagnosis of exocrine pancreatic dysfunction is based on typical findings in clinical histories and clinical signs. It is confirmed with pancreatic function tests. When it is needed to verify the underlying pathological process causing the clinical signs, morphologic examination of the pancreas is performed.

234.1.2.1 Clinical History and Clinical Signs

Typical clinical signs of EPI include yellowish or gray feces, increased fecal volume and defecation frequency, weight loss, and flatulence. Other signs include abnormally increased appetite; poorly digested, loose, and pulpy feces; and occasional coprophagia. Nervousness or aggressiveness have also been reported, and these are suspected to result from abdominal discomfort due to increased bowel movements and gas formation. Severe watery diarrhea is usually only temporary. Poor hair coat has also been reported in dogs with EPI.[4] Although these clinical signs are typical for EPI, they are not pathognomonic for the disease, as small intestinal disease may cause similar maldigestion signs.

234.1.2.2 Clinical Pathologic Evaluation

Results of standard laboratory analysis are usually not helpful in diagnosing of EPI. Some dogs have hypocholesterolemia and increases in serum alanine aminotransferase activities. This may reflect hepatocyte damage secondary to increased uptake of hepatotoxic substances through small intestinal mucosa. Serum amylase and lipase concentrations are of no value in diagnosing EPI.[1]

234.1.2.3 Pancreatic Function Tests

Various pancreatic function tests have been shown to be valuable in confirmation of the diagnosis of clinical EPI. The value of these tests lies of their ability to distinguish whether the clinical signs are due to exocrine pancreatic dysfunction or to small intestinal disease.[1]

234.1.2.4 Serum Trypsin-like Immunoreactivity

The measurement of serum canine trypsin-like immunoreactivity (cTLI) by radioimmunoassay has become one of the most commonly used pancreatic function tests to diagnose canine EPI. Serum cTLI measurement is species-and pancreas-specific. It measures only pancreatic trypsin and trypsinogen that has entered the bloodstream directly from the pancreas. The reference range for cTLI in healthy dogs is more than 5.0 to 35 μg/L.

Abnormally low serum cTLI concentrations (<2.5 μg/L), in association with the typical clinical signs of maldigestion, are considered highly diagnostic for severe EPI. Because trypsinogen is not absorbed from the intestinal lumen, intestinal disease does not affect cTLI measurement. Serum cTLI measurement is a practical test since usually only a single sample is needed to confirm the clinical diagnosis of EPI. Fasting samples (8 to 12 hours) are recommended as a postprandial increase of serum trypsinogen levels, even though slight and transient, may occur. Because trypsinogen is eliminated by glomerular filtration, renal dysfunction associated with pancreatic disease can cause a rise in serum cTLI.[11]

234.1.2.5 Fecal Proteolytic Activity

Low fecal proteolytic activity has been reported in dogs with severe EPI. The reliability of different fecal proteolytic activity tests varies. The X-ray film test is a simple method but not reliable. More valuable, semiquanititative methods for measuring fecal proteolytic activity are the azocasein method and radial enzyme diffusion into agar containing a casein substrate. Fecal proteolytic activity should be measured in repeated samples because of considerable daily variations in results and because healthy dogs may occasionally pass feces with low proteolytic activity. To prevent incorrect abnormal results, fecal proteolytic activity has been measured after giving dogs raw soybean in their food and determining activities by a radial enzyme diffusion method in fecal samples for 3 days (soybean stimulation test).[12]

234.1.2.6 Fecal Elastase Activity

A new fecal test for diagnosing exocrine pancreatic dysfunction is the measurement of fecal elastase using the ELISA method. Canine fecal elastase is a species-and pancreas-specific test. A single fecal sample is adequate for diagnosing severe EPI and an elastase concentration of less than 10 μg/g in association with clinical signs of EPI is suggestive of severe dysfunction. A drawback of this test is that abnormal results can occasionally be found in normal dogs.[13]

234.1.2.7 Diagnosis of Subclinical EPI and Partial PAA

Serum cTLI values within the subnormal range of 2.5 to 5.0μg/L have been shown to reflect decreased pancreatic function and can be used for the early diagnosis of EPI. In breeds predisposed to PAA, cTLI measurement can be used for diagnosis of the subclinical disease. Repeatedly subnormal serum cTLI values in dogs showing no typical signs of EPI indicate subclinical EPI and suggest partial PAA.

Despite low fasting serum cTLI values, the reserve secretory capacity of the pancreas may prevent the appearance of clinical signs. Some of the dogs with a subclinical disease may have cTLI values of less than 2.5μg/L. To diagnose subclinical disease, repeated cTLI measurements are needed to increase the accurance of the diagnosis. One single subnormal value is not diagnostic for pancreatic dysfunction. In addition

overlapping of cTLI results between subclinical and normal dogs is possible. A normal cTLI (>5.0 µg/L) does not exclude mild to moderate pancreatic dysfunction.[8]

234.1.2.8 Verification of Underlying Pathologic Process

Pancreatic morphologic examination is performed when it is necessary to identify the underlying pathologic process causing pancreatic dysfunction. In dogs with either partial or end-stage PAA, the clinical histories, clinical signs, and results of function tests are usually highly suggestive of the underlying pathologic process. With breeds predisposed to PAA, morphologic examination is rarely needed. Morphologic examination can be useful in atypical cases. The disadvantage of laparotomy and laparoscopy is that they are invasive methods. Further, the morphologic changes in the pancreas are usually unevenly distributed, thus the severity of findings is greatly dependent on the site of biopsy. Pancreatic biopsies can be taken by laparotomy to dissect a small pancreatic sample or by laparoscopy using crushing forceps.[3]

234.1.3 Treatment

234.1.3.1 Treatment and Prognosis of Subclinical EPI

Asymptomatic dogs with partial PAA and subclinical EPI do not need any treatment. The speed of the progression of atrophy from subclinical to clinical phase is variable, and the factors affecting the speed of progression are not yet identified. Early immunosuppressive treatment to halt the progression of the autoimmune mediated tissue destruction has been considered to prevent the clinical disease.

1493

Long-term follow-up of the dogs with partial PAA and subclinical EPI showed that the value of immunosuppressive treatment in slowing acinar atrophy is questionable. Dogs may stay in the subclinical phase for years or sometimes for life with or without medication. No diagnostic markers predicting which dogs will develop clinical disease have been found, thus immunosuppressive treatment is not recommended.[14] Some dogs with partial PAA may show chronic or intermittent gastrointestinal signs not typical for EPI. The gastrointestinal signs may be due to subnormal pancreatic function or an underlying small intestinal disease or a combination of both. The diagnostic workup and treatment for possible concurrent small intestinal disease is recommended. If no underlying small intestinal disorder is identified, a trial treatment with pancreatic enzymes should be initiated.[14]

1494

234.1.3.2 Treatment and Prognosis of Clinical EPI

234.1.3.2.1 Enzyme replacement therapy

When clinical signs of EPI appear, enzyme replacement therapy is indicated. Basic treatment for EPI is supplementation of each meal with enzyme extracts. Various pancreatic enzyme extracts are available. In dogs, the highest enzyme activity in the duodenum has been obtained with nonenteric-coated supplements; like raw chopped pancreas or powdered enzymes. In clinical trials, these two supplements have proved to be equally effective in controlling clinical signs. The choice between the preparations is therefore based on practical properties, availability, and costs. In many countries the use of raw pancreas is not allowed because of possibilities of zoonotic diseases. The maintenance dosage for the powdered enzyme preparation is usually 1 tsp/meal, and for raw, chopped pancreas 50 to 100 g/meal for dogs that

weigh 20 to 35 kg. The value of enteric-coated supplements has been demonstrated to be limited in dogs because of the delayed gastric emptying of the preparations.[1,15]

234.1.3.2.2 Supportive treatments

When the treatment response to nonenteric-coated enzyme supplements and ordinary dog food is not satisfactory, the supportive therapies should be considered.

Orally administered enzymes are largely destroyed by gastric acid and despite accurate enzyme therapy the digestive capacity does not return to normal. In some dogs the increase of enzyme dosage or change to another nonenteric-coated enzyme supplement may be beneficial. Inhibition of gastric acid secretion by H_2-antagonist has shown some positive effects. The routine use of H_2-antagonists is not recommended but is indicated when response to enzyme treatment is poor. Preincubation enzymes in food before feeding and supplementing with bile salts or antacids have been recommended to increase the efficiency of enzyme supplementation, but with no proven efficiency.[1]

234.1.3.2.3 Dietary modification

Clinical feeding studies have shown controversial results on the actual benefits of using special diets. In general, no dietary modification is needed and the dogs may continue to be fed with their ordinary food. However, special attention should be paid to individual needs and radical dietary changes should be avoided.[1,15]

In those dogs that do not show the satisfactory treatment response, dietary modification may be useful. A highly digestible, low-fiber and moderate-fat diet has shown to be able to alleviate such clinical signs as flatulence, borborygmi, increased fecal volume, and defecation frequency. Highly digestible diets may be of particular value in the initial treatment until nutritional status has improved. A low-fat diet has been considered to be valuable because enzyme supplements alone are unable to restore normal fat absorption. Lipase is most easily destroyed by gastric acid. Fat absorption may be affected also by the bacterial deconjugation of bile salts in a small intestinal disease, producing metabolites, which in turn may result in diarrhea. Dietary sensitivities may be a consequence of EPI. Therefore hypoallergenic diets may benefit some dogs with EPI, especially in the early treatment. No obvious clinical benefits have been demonstrated with adding medium-chain triglycerides to food.

234.1.3.2.4 Antibiotics

Antibiotics are the most commonly used adjunctive medications in treatment of EPI. Small intestinal bacterial overgrowth is common in dogs with EPI before and during enzyme replacement treatment. An increased amount of substrate for bacteria in the small intestinal lumen, a lack of bacteriostatic factors present in normal pancreatic juice, and changes in intestinal motility and immune functions are possible reasons for an abnormal accumulation of bacteria in the small intestine of dogs with EPI. Antibiotics have particularly been used during initial treatment in cases of poor treatment response to enzymes alone and when clinical signs, such as diarrhea, borborygmus, and flatulence have recurred during long-term treatment. Antibiotics reported to be effective are tylosin, oxytetracyclin, and metronidazole. Usually treatment with antibiotics for 1 to 3 weeks is effective.[1,15]

234.1.3.2.5 Cobalamin

Cobalamin deficiency is common in dogs with EPI. This deficiency is partly due to an increased uptake of cobalamin by intestinal bacteria and partly because of the lack of pancreatic intrinsic factor, demonstrated to have a major role in the absorption of cobalamin. Enzyme supplementation alone has not been found to be helpful for increasing serum cobalamin levels. Parenteral cobalamin treatment is needed when low serum cobalamin values are detected. The clinical signs of cobalamin deficiency are still poorly documented in canine EPI. The doses for cobalamin recommended are 250 to 500 μg parenterally. The vitamin treatment should be repeated based on the serum levels.[1,15]

234.1.3.2.6 Other supportive treatments

Malabsorption of fat soluble vitamins may be suspected in dogs with EPI. The clinical importance of vitamin A, D, E, K deficiency in dogs has not been reported. When treatment responses to enzymes and supportive therapies are insufficient, concomitant small intestinal disease and lymphoplasmacytic enteritis should be suspected. To date, no comprehensive studies on EPI and associated small intestinal diseases have been published. Glucocorticoids treatment is not recommended.[1]

234.1.4 Prognosis

Usually a lifelong enzyme treatment is needed. Response to enzyme treatment is usually seen during the first weeks of treatment, with weight gain, decrease in polyphagia and fecal volume, and cessation of diarrhea. The level of treatment response achieved during the initial treatment period seems to remain rather stable. Although some dogs show short relapses of clinical signs, usually no permanent deterioration of clinical condition is seen during the long-term enzyme treatment.[1,15]

During long-term treatment with nonenteric-coated supplements, 50% of dogs are almost totally controlled. However, despite similar treatment regimes, the treatment response has been shown to be variable, and about 20% of EPI dogs have a poor response. Although it is not always possible to eliminate all the signs, good resolution is found especially for more serious signs such as continuous diarrhea and malnutrition. Why some clinical signs are incompletely controlled and others so variable is not completely understood.

About 20% of the dogs diagnosed for EPI are euthanized during the first year after diagnosis. The most common reason for euthanasia is poor response to treatment. Another reason is owner reluctance for expensive and lifelong treatment.[15,16] A rare, but severe complication of EPI is mesenteric torsion. The etiology of mesenteric torsion remains unclear. Today mesenteric torsion is rare, probably because of the improvement of treatment regimes for EPI.

1494

1495

234.2 FELINE EXOCRINE PANCREATIC INSUFFICIENCY

Exocrine pancreatic insufficiency (EPI), although uncommon, does occur in cats and therefore should be considered in the differential diagnosis for weight loss and diarrhea in this species. Although the pathophysiology, etiology, diagnosis, and treatment are similar to those of EPI in dogs, there are some important differences.[17] Chronic pancreatitis is the most common cause of EPI in the cat. Rare cases of EPI without pancreatitis have been reported due to duct obstruction associated with *Eurytrema procyonis* infestation.

Adenocarcinomas of the exocrine pancreas can lead to obstruction of the pancreatic duct, followed by atrophy of acinar tissue. Finally, the authors are aware of several reports of pancreatic acinar atrophy (PAA) that is histologically indistinguishable from that so commonly observed in dogs; whether the pathophysiology in such cases is the same as in dogs is not known.[17]

Classical clinical signs include loose, malodorous, and voluminous stools, with poor body condition. Weight loss, even in untreated cases, is rarely as extreme as in untreated dogs. As in dogs, polyphagia is not an invariable sign. It should be emphasized that most cats with polyphagia, weight loss, and diarrhea are ultimately diagnosed as having small intestinal disease associated with severe cobalamin deficiency. These cases are clinically indistinguishable from those with EPI. Indeed, the frequent occurrence of severely subnormal serum cobalamin concentrations, and somewhat less commonly serum folate concentrations, in cats with EPI (abnormalities seen far less often in dogs), indicate that many have severe concurrent small intestinal disease leading to vitamin malabsorption. Cats with EPI may exhibit a greasy, wet-looking and generally unkempt hair coat, especially in the perineal region, which may in part reflect severe cobalamin deficiency.

The differential diagnosis for cats with weight loss, diarrhea, and changes in appetite include chronic small intestinal disease (most commonly inflammatory bowel disease), hyperthyroidism, and diabetes mellitus. In older cats these conditions may be concurrent. Owing to the underlying pathophysiology of EPI in cats, diabetes mellitus is a far more frequent complication of EPI than it is in dogs. It has been reported that more than 50% of cats with diabetes mellitus have pancreatitis. Although it is unknown if this is a cause-and-effect or coincidental relationship, some of these patients do develop EPI.

Results of hematologic and serum biochemical testing, and abdominal radiography or ultrasonography are generally unremarkable, although lymphopenia, lymphocytosis, neutrophilia, eosinophilia, and elevations of hepatic enzymes have been reported sporadically. Many specific tests to evaluate exocrine pancreatic function in cats are either impractical or unreliable, including the bentiromide absorption test, plasma turbidity, microscopic examination of feces for undigested fat, starch, or muscle fibers. Fecal proteolytic activity (FPA) can be determined by either azocasein-or azoalbumin-based methods, or by a radial enzyme diffusion method, and most cats with EPI have undetectable FPA. Unfortunately, this finding is not specific for EPI; FPA is somewhat labile, and few diagnostic laboratories determine FPA using reliable assay methods. Furthermore, the requirement to collect and assay several fecal samples makes this approach expensive and inconvenient. Fortunately, a highly reliable and economical species specific radioimmunoassay for feline trypsin-like immunoreactivity (fTLI) has been developed and validated, and shown to be accurate in the diagnosis of feline EPI.[18,19] Similar to the situation in dogs, severely decreased serum fTLI concentration is diagnostic for EPI in the cats. The fTLI is presently only run at the laboratory directed by two of the authors, but serum fTLI is very stable and samples can readily be shipped worldwide directly to this laboratory. Numerous commercial laboratories will also forward samples to this laboratory on request.

234.2.1 Treatment

Cats with EPI will at least require dietary supplementation with pancreatic enzymes for resolution of clinical signs. It is important to recognize that in most cats, treatments in addition to enzyme supplementation will be required to achieve an optimal response. Dried powdered extracts (give 0.5 teaspoonfuls per meal) of porcine pancreas are available (e.g., Viokase, Pancrezyme, PancreVed). Tablets, capsules, and enteric-coated formulations are usually less effective. Raw pancreas (1 to 2 oz per meal) can also be offered and can be stored frozen for several months prior to feeding. Preincubation of the food with pancreatic enzymes, supplementation with bile salts, or concurrent antacid therapy are unnecessary.[17]

Since cats with EPI almost always have extreme depletion of total body cobalamin stores and undetectable serum cobalamin, it is not surprising that parenteral cobalamin (100 to 250 μg subcutaneously once weekly) is often beneficial. Uncorrected cobalamin deficiency may lead to villous atrophy, intestinal inflammation, and malasborption, with resultant failure to respond to pancreatic enzymes alone. Serum folate concentration is also subnormal in many affected cats, and in some cases serum concentrations can be very low. Oral folate supplementation (400 μg daily orally) will rectify any deficiency. Serum cobalamin and folate concentrations should be routinely evaluated in cats with suspected EPI and periodically assessed following initiation of therapy since deficiencies often recur. Some affected cats also have hypovitaminosis K, and if untreated this can lead to bleeding disorders, which can be fatal if they go unrecognized.

Some cats will not respond appropriately to enzyme supplementation and cobalamin and/or folate supplementation. These cats usually have concurrent small intestinal disease, perhaps associated with abnormal proliferation of bacteria in the upper intestine. In these cases treatment with oral prednisolone (initial dose 5 mg twice daily for 1 to 2 weeks) and/or oral metronidazole (100 mg twice daily for 2 to 4 weeks) is often beneficial. Long-term treatment with either antibiotics nor glucocorticoid is usually not required.

235 CHAPTER • 235 Acromegaly and Pituitary Dwarfism

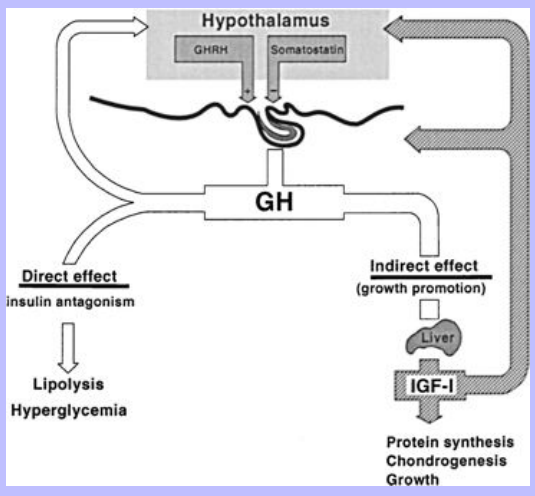
Hans S. Kooistra

235.1 GROWTH HORMONE

Growth hormone (GH) is a rather large single-chain polypeptide with a molecular weight of approximately 22 kDalton. The amino acid sequence of GH varies considerably between different species. The amino acid sequence of canine GH is, however, identical to that of porcine GH.[1]

Like the other hormones of the pituitary anterior lobe, GH is secreted in a pulsatile fashion. Pituitary GH secretion is regulated mainly by the opposing actions of the stimulatory hypothalamic peptide GH-releasing hormone (GHRH) and the inhibitory hypothalamic peptide somatostatin (Figure 235-1). The GH pulses predominantly reflect the pulsatile delivery of GHRH, whereas GH levels between pulses are primarily under somatostatin control. The release of GHRH and somatostatin is controlled by complex neural regulatory mechanisms. GH release can also be elicited by synthetic GH secretagogues. These GH secretagogues exert their effect on GH release by acting through receptors different from those for GHRH. In 1999 Kojima et al characterized the endogenous ligand for these receptors and called it *ghrelin*.[2] The main source of circulating ghrelin, which also is stimulatory for canine GH[3], appears to be the stomach.

Figure 235-1 The pituitary secretion of GH is under inhibitory (somatostatin) and stimulatory (GHRH) hypothalamic control and is also modulated by negative feedback control of IGF-I and GH itself. The direct catabolic (diabetogenic) actions of GH are shown on the left side of the figure, and the indirect anabolic actions are shown on the right. (Redrawn from Rijnberk A, editor: *Clinical endocrinology of dogs and cats*, Dordrecht, The Netherlands, 1996, Kluwer Academic Publishers.)



In the dog, circulating GH not only originates from the pituitary but also may be of mammary origin. In the 1970s and 1980s it was shown that administration of progestins to dogs could lead to elevated plasma GH levels. These progestin-stimulated plasma GH levels do not have a pulsatile secre-tion pattern, are not sensitive to stimulation with GHRH or the α-adrenergic agonist clonidine, and are not inhibited by somatostatin, which points to autonomous secretion. Furthermore it was shown that the progestin-induced elevated plasma GH levels do not decrease after hypophysectomy, which indicates that this GH originates from an extrapituitary site. In 1994 Selman et al published that the progestin-induced GH production in the dog originates from foci of hyperplastic ductular epithelium of the mammary gland.[4] It was also demonstrated that mammary GH is biochemically identical to pituitary GH and that the gene encoding GH in the mammary gland is identical to the gene in the pituitary gland.

The pulsatile secretion pattern of GH changes during progression of the luteal phase of the estrous cycle of healthy bitches, with higher basal GH secretion and less GH secreted in pulses during stages with a high plasma progesterone concentration.[5] It is likely that this is caused by a partial suppression of pituitary GH release by progesterone-induced GH production in the mammary gland. This indicates that progestin-induced mammary GH production is not just an aberration but a normal physiologic event during the luteal phase of the estrous cycle in healthy cyclic bitches. The GH-receptor is also present in the mammary gland, which supports the concept that the progesterone-induced mammary GH production may promote the physiologic proliferation of mammary gland tissue and the preparation for lactation during the luteal phase by local autocrine and paracrine effects. High concentrations of GH have also been found in mammary secretions, particularly in colostrum.[6] The high GH levels in colostrum, often 100 to 1000 times higher than plasma GH levels, may be of importance for the gastrointestinal development of neonates. The progestin-induced mammary GH production may also play a role in mammary gland tumor development or tumor progression.[7]

The effects of circulating GH can be divided into two main categories: rapid catabolic actions and slow (long-lasting) hypertrophic actions. The acute catabolic actions are mainly due to insulin antagonism and result in enhanced lipolysis, gluconeogenesis, and restricted glucose transport across the cell membrane. The net effect of these catabolic actions is promotion of hyperglycemia. The slow anabolic effects are mainly mediated via insulin-like growth factors (IGFs). IGFs are produced in many different tissues, and in most of these tissues they have a local (paracrine or autocrine) growth-promoting effect. The main source of circulating IGF-I is the liver. The chemical structure of IGFs has about 50% sequence similarity with insulin. In contrast to insulin, IGFs are bound to binding proteins (IGFBPs). As a result of this binding to carrier proteins they have a prolonged half-life, which is consistent with long-term growth-promoting effects. IGFs are important determinants in the regulation of body size, by stimulating protein synthesis, chondrogenesis, and growth. There is increasing evidence that GH exerts its growth-promoting effect not only via IGFs but also by a direct effect on the cells.

1498 1499

IGF-I exerts an inhibitory effect on GH release, by stimulating the release of somatostatin and by a direct inhibitory influence at the pituitary level. In addition, GH itself has a negative feedback effect at the hypothalamic level (see Figure 235-1).

235.2 ACROMEGALY

235.2.1 Pathogenesis

Acromegaly is a syndrome of bony and soft tissue overgrowth and insulin resistance due to excessive GH secretion. The pathogenesis of acromegaly is completely different in dogs and cats. In middle-aged and elderly

female dogs, either endogenous progesterone (luteal phase of the estrous cycle) or exogenous progestins (used for estrus prevention) may give rise to GH hypersecretion of mammary origin. In the cat, acromegaly is caused by an acidophilic pituitary adenoma that secretes excessive amounts of GH. The condition is encountered most often in middle-aged and elderly, predominantly male, cats. Progestins may also induce GH expression in mammary tissue in the cat, but the hormone does not seem to reach the systemic circulation.

235.2.2 Clinical Manifestations

Signs and symptoms of GH hypersecretion tend to develop slowly and are characterized initially (particularly in the dog) by soft tissue swelling of the face and the abdomen. In some acromegalic dogs severe hypertrophy of soft tissues of the mouth, tongue (Figure 235-2), and pharynx causes snoring and even dyspnea. Affected dogs may also have polyuria (and sometimes polyphagia). The polyuria is usually without glucosuria, but manifest diabetes mellitus can develop due to insulin resistance. Physical examination may reveal thick skin folds, (especially in the neck), prognathism, and wide interdental spaces. Prolonged GH excess also leads to generalized visceromegaly, which results in abdominal enlargement. Laboratory investigations in dogs with acromegaly may demonstrate hyperglycemia and/or an abnormal glucose tolerance test. Plasma alkaline phosphatase activities may also be increased. This may, in part, be due to the intrinsic glucocorticoid activity of progestins.

Figure 235-2 The mouth of a 4-year-old beagle dog with progestin-induced GH excess. Note the hyperplasia of the gingiva, the widening of the interdental spaces and the relatively large tongue.

The physical changes in cats tend to be less pronounced than in dogs. The head may also become somewhat massive and may have rather pronounced features. The most common problem in acromegalic cats is (severe) insulin-resistant diabetes mellitus. There may also be proliferative changes that lead to a progressive degenerative arthropathy with lameness. Affected cats may have dyspnea due to hypertrophic cardiomyopathy and subsequent heart failure. Finally, when the pituitary adenoma causing acromegaly becomes large, it may cause neurological signs. For many acromegalic cats the only routine laboratory changes are the hyperglycemia and glucosuria due to the secondary diabetes mellitus.

235.2.3 Diagnosis

Acromegaly is an uncommon condition in diabetic cats. Conversely, insulin resistance or "apparent insulin resistance" is quite common in cats with diabetes mellitus. Thus the diagnosis of acromegaly should be considered only after all other causes for blood glucose concentrations that are persistently increased are eliminated from the differential diagnosis. A complete discussion of feline diabetes mellitus and its management strategy is provided in Chapter 241.

The diagnosis of GH excess can generally be established by measuring basal plasma GH levels. The basal plasma GH level in acromegalic animals often exceeds the upper limit of the reference range (6 μg/L). However, if the disease is mild or just beginning, the basal plasma GH concentration may be only slightly increased. Conversely, a high value may be the result of a secretory pulse in a normal animal. Nonresponsiveness of normal or increased plasma GH concentrations to stimulation may further support the diagnosis.[8] Because of the variation in amino acid sequence of GH in different species, GH should be determined in a homologous radioimmunoassay. Fortunately, feline GH can be measured reliably in a radioimmunoassay developed for the dog.

Measurement of plasma IGF-I concentration may also contribute to the diagnosis. As reviewed, the circulating IGF-I concentration is GH-dependent. Being bound to proteins, the IGF-I concentration is less subject to fluctuation than is GH. However, there is some overlap in plasma IGF-I concentrations between healthy animals and those with acromegaly. In addition, it has been reported that there may be increases in plasma IGF-I levels in diabetic cats unrelated to acromegaly. The amino acid sequence of IGF-I is less species specific than that of GH and therefore IGF-I can be determined in a heterologous (human) assay.

Excessive GH secretion in cats is due to a pituitary adenoma. Consequently, when acromegaly has been demonstrated in a cat, the pituitary should be visualized by computed tomography (CT) or magnetic resonance imaging (MRI) (Figure 235-3).

235.2.4 Treatment

Acromegaly in dogs can be treated easily and effectively by discontinuation of exogenous progestins and/or ovario(hyster)-ectomy. The animal may then change dramatically due to the reversal of the soft tissue changes. The bony changes appear to be irreversible but do not seem to cause problems. For dogs in which the GH excess did not lead to complete exhaustion of the pancreatic β-cells, the elimination of the progesterone source by ovario(hyster)ectomy may prevent persistent diabetes mellitus. In case of recent administration of exogenous progestins, synthetic progesterone receptor blockers may be useful, but experience with long-term administration of this class of drugs is lacking. In the end one may even decide for total mammectomy.

1499

In cats treatment should be directed at the pituitary tumor. In principle, there are three options: hypophysectomy, irradiation, and medication. There is little experience with any of the three. Medical treatment with drugs such as dopamine agonists does not seem to be effective. Long-acting somatostatin analogues have been shown to lower circulating GH levels in a single cat.[9] In others the drug was not effective. Therefore due to expense and lack of efficacy, it is questionable whether this drug will be used in clinical practice. The development of GH-receptor antagonists such as pegvisomant used in humans may hold promise for dogs and cats with acromegaly. Cobalt irradiation may result in temporary improvement and in (transient) discontinuation of insulin therapy.[10] Transspheniodal hypophysectomy has been performed

1500

successfully in cats with hyperadrenocorticism due to a pituitary corticotroph adenoma[11] and may also become an effective treatment option for cats with acromegaly.

(From Rijnberk A, editor: *Clinical endocrinology of dogs and cats,* Dordrecht, The Netherlands, 1996, Kluwer Academic Publishers.)

235.3 PITUITARY DWARFISM

235.3.1 Pathogenesis

Any defect in the organogenesis of the pituitary gland may result in a form of isolated or combined pituitary hormone deficiency. Congenital GH deficiency or pituitary dwarfism is the most striking example of pituitary hormone deficiency. Congenital GH deficiency has been mentioned to occur in cats and different dog breeds.[12] However, the condition is encountered most often as a simple, autosomal recessive inherited abnormality in the German shepherd dog. Inherited pituitary dwarfism in German shepherd dogs is due to combined pituitary hormone deficiency. German shepherd dwarfs have a combined deficiency of GH, TSH, and prolactin together with impaired release of gonadotropins. In contrast, ACTH secretion in German shepherd dwarfs is preserved (Figure 235-4).[13]

Originally, pituitary dwarfism in the German shepherd dog breed has been ascribed to pressure atrophy of the pituitary anterior lobe by cyst formation in Rathke's pouch. Indeed, in most German shepherd dwarfs pituitary

cysts are present. However, at a young age German shepherd dwarfs sometimes have no or only a very small pituitary cyst, unlikely to be responsible for pressure atrophy. Also the finding that the ACTH secretion is preserved in German shepherd dwarfs argues against cyst formation in Rathke's pouch as the primary cause of pituitary dwarfism in this breed. It is therefore more likely that the disorder is caused by a primary failure of differentiation of the craniopharyngeal ectoderm into normal tropic-hormone-secreting pituitary cells. In this view in German shepherd dwarfs the cyst formation in Rathke's pouch is rather a consequence of an underlying genetic defect than the cause of dwarfism.

235.3.2 Clinical Manifestations

By 2 to 5 months of age, pituitary dwarfs usually have proportionate growth retardation and an abnormally soft and woolly hair coat (Figure 235-5). The latter is due to retention of lanugo or secondary hairs and lack of primary or guard hairs. The lanugo hairs are easily epilated and there is gradual development of truncal alopecia, beginning at the points of wear. The alopecia typically spares the head and extremities. The skin becomes progressively hyperpigmented and scaly. Secondary bacterial infections of the skin are quite common. In male dwarfs unilateral or bilateral cryptorchidism is common, whereas in female dwarfs persistent anestrus is common. These abnormalities may be ascribed to the impaired release of gonadotropins.

Initially, pituitary dwarfs are usually lively and alert. With time the animals develop inappetence and become less active. This situation is usually reached at the age of two or three years and has been ascribed to secondary hypothyroidism and impaired renal function.[9]

235.3.3 Diagnosis

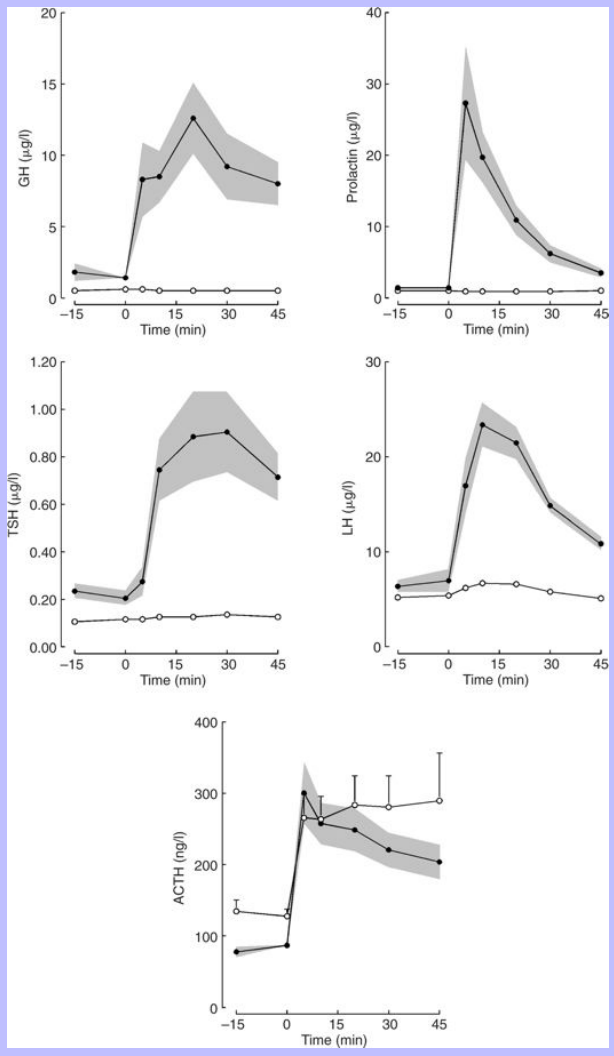
Although the physical characteristics of pituitary dwarfism may be obvious, other endocrine and nonendocrine causes of growth retardation and alopecia have to be excluded.

Routine laboratory examination usually does not reveal abnormalities, except for an elevated plasma creatinine concentration. GH deficiency is associated with maldevelopment of the glomeruli. In addition, renal function may be impaired due to a functionally decreased glomerular filtration rate as a result of the deficiencies of GH and thyroid hormones. As indicated above (see also Figure 235-4) the combined pituitary hormone deficiency includes secondary hypothyroidism. Consequently, a low plasma TSH concentration in combination with a plasma thyroxine level below the reference range is a common finding in pituitary dwarfs. Plasma IGF-I concentrations are also decreased in pituitary dwarfs, even when age and body size are taken into account. Nevertheless, a definitive diagnosis should rely on measurements of circulating GH concentration.

Since basal plasma GH values may also be low in healthy animals, the definitive diagnosis GH deficiency is based upon the results of a stimulation test. For this purpose GHRH (1 μg/kg body weight) or α-adrenergic drugs, such as clonidine (10 μg/kg body weight) or xylazine (100 μg/kg body weight), can be used. The plasma GH concentration should be determined immediately before and 20 to 30 minutes after intravenous administration of the stimulant. In healthy dogs, plasma GH concentrations should increase at least two-to fourfold after administration of the stimulant. In dogs with pituitary dwarfism there is no significant rise in circulating GH concentrations. Supra-pituitary stimulation with corticotropin-releasing hormone (CRH), thyrotropin-releasing hormone (TRH), and gonadotropin-releasing hormone (GnRH) may reveal the presence of other pituitary hormone deficiencies.

Diagnostic imaging of the pituitary area (CT or MRI) often reveals the presence of pituitary cysts in dogs with congenital GH deficiency. In the majority of young dogs with pituitary dwarfism the pituitary is quite small, in spite of the presence of cysts.[13] This is compatible with pituitary hypoplasia, that is, a lack of endocrine cells in the pituitary anterior lobe. As pituitary dwarfs age the pituitary cysts become larger.[14] It is important to understand that healthy dogs, especially brachycephalic dogs, may have pituitary cysts. Consequently, a definitive diagnosis of pituitary dwarfism cannot be based solely upon the presence of a cyst.

Figure 235-4 Results of a combined pituitary anterior lobe function test (mean and SEM) in eight German shepherd dogs with dwarfism (○) and in eight healthy beagle dogs (•). (From Kooistra HS et al: Combined pituitary hormone deficiency in German shepherd dogs with dwarfism, *Domest Animal Endocrinol* 19:177, 2000.)



235.3.4 Course

The long-term prognosis of German shepherd dwarfs is usually poor without treatment. By the age of 3 to 5 years the animal has usually become a bald, thin, and dull dog. These changes may be due to (1) progressive loss of pituitary functions, (2) continuing expansion of pituitary cysts, and (3) progressive renal failure. At this stage owners usually request euthanasia for their dog, if they have not done so long before this.[9] 1501 1502

Figure 235-5 A 6-month-old female German shepherd dog with growth retardation, retention of secondary hairs (puppy coat), and lack of primary hairs due to pituitary dwarfism.

235.3.5 Treatment

The long-term prognosis for German shepherd dwarfs is poor primarily because of the lack of an adequate therapy. Canine GH is not available for therapeutic use and hence there have been attempts to treat dogs that have congenital GH deficiency with porcine or human GH. However, antibody formation precludes the use of biosynthetic human GH.[15] As indicated above the amino acid sequence of porcine GH is identical to that of canine GH[1], and therefore porcine GH is an option.

The recommended subcutaneous starting dose for heterologous GH is 0.1 to 0.3 IU per kg body weight three times per week for 4 to 6 weeks. This treatment may result in GH excess and consequently side effects such as diabetes mellitus may develop. Weekly monitoring of the plasma concentrations of IGF-I and glucose is therefore of utmost importance. Long-term dose rates after the induction period should also depend on measurements of the plasma concentration of IGF-I. Treatment often does not result in a significant increase in body size, because the growth plates in most dwarfs have already closed or are about to close at the time

GH treatment is initiated. The hairs that grow back are primary lanugo hairs; growth of guard hairs is variable.[12]

The demonstration of the ability of progestins to induce the expression of the GH gene in the canine mammary gland and the subsequent release of this GH into the systemic circulation has raised the possibility of treating dogs with congenital GH deficiency with progestins. Treatment of young German shepherd dwarfs with subcutaneous injections of medroxyprogesterone acetate in doses of 2.5 to 5.0 mg per kg body weight, initially at 3-week intervals and subsequently at 6-week intervals, has resulted in some increase in body size and the development of a complete adult hair coat. Parallel with the physical improvements, plasma IGF-I concentrations rose sharply, whereas plasma GH concentrations did rise but never exceeded the upper limit of the reference range.[14] Also treatment of pituitary dwarfs with proligestone has been reported to result in the development of an adult hair coat, increased body weight, and elevated plasma IGF-I concentration.[16]

Treatment of dogs with congenital GH deficiency with progestins may give rise to side effects, such as recurrent periods of pruritic pyoderma and, infrequently, development of mammary tumors. As with the treatment using heterologous GH, monitoring of the plasma concentrations of IGF-I and glucose is important to prevent diabetes mellitus and acromegaly. Bitches should be ovariohysterectomized before the start of the progestin treatment, to prevent development of cystic endometrial hyperplasia. Finally, thyroid hormone replacement should be part of the treatment schedule.

236 CHAPTER • 236 Diabetes Insipidus

Ad Rijnberk

Diabetes insipidus refers to the passage of large quantities of dilute urine and is actually synonymous with polyuria. In central diabetes insipidus the polyuria results from a lack of sufficient vasopressin to concentrate urine. The disease is characterized by three primary findings: (1) dilute urine despite strong osmotic stimuli for vasopressin secretion, (2) absence of renal disease, (3) a rise in urine osmolality following the administration of vasopressin.

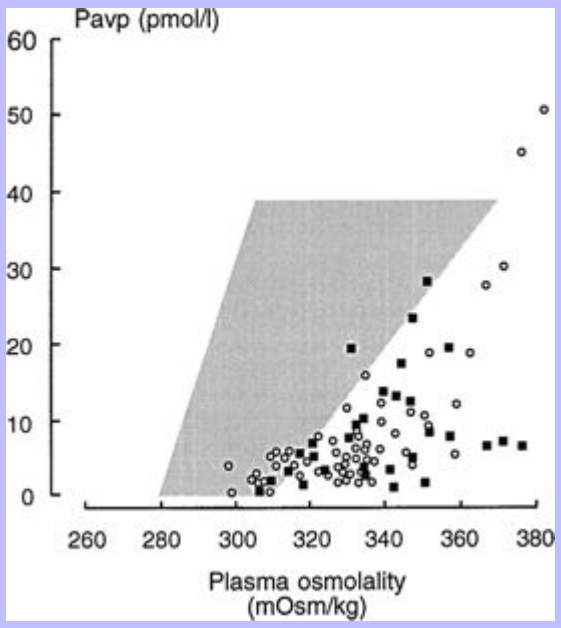
236.1 VASOPRESSIN

Vasopressin is released by the posterior lobe or neurohypophysis, which is an extension of the ventral hypothalamus. Together with the other neurohypophyseal hormone oxytocin, vasopressin is synthesized in both the supraoptic and paraventricular nuclei of the hypothalamus, from which axons extend through the pituitary stalk to the posterior pituitary. The hormones vasopressin and oxytocin are formed by separate neurons and migrate down the axons as part of precursor proteins. They are stored in secretory granules within the nerve terminals in the neurohypophysis and are released by exocytosis into the bloodstream in response to appropriate stimuli. As in most mammals, in dogs and cats arginine-vasopressin (AVP) or antidiuretic hormone (ADH) (in pigs: lysine-vasopressin) plays a vital role in water conservation. Oxytocin stimulates uterine contractions and milk ejection.

The nonapeptide AVP is synthesized as part of a large precursor molecule that is composed of a signal peptide, the hormone, a carrier protein termed neurophysin and a glycopeptide. The major determinant of the release of vasopressin is plasma osmolality. In addition, significant changes in circulating blood volume may influence the setting of the osmoregulation. Specialized neurons called *osmoreceptors* are concentrated in the anterolateral hypothalamus, which is near but separate from the supraoptic nuclei. This area is supplied with blood by small perforating branches of the anterior cerebral arteries. The major role of vasopressin is to regulate body fluid homeostasis by affecting water reabsorption. The antidiuretic effect is achieved by promoting the reabsorption of solute-free water in the distal and collecting tubules of the kidney. The cellular mechanism of AVP activity in the renal tubule involves binding to specific contraluminal V_2-receptor sites, an adenylate cyclase response, and phosphorylation of membrane proteins that lead to transient insertion of water channels in the luminal membrane of the cell. In the presence of these channels water molecules can move passively along an osmotic gradient, that is, from the distal and collecting tubules to the hypertonic renal medulla.

Cations, drugs, and hormones can influence the action of AVP and thereby cause polyuria. Calcium inhibits the adenylate cyclase response to vasopressin. Glucocorticoids also interfere with the action of AVP, although in dogs loss of reactivity of the osmoreceptor system also seems to contribute to corticosteroid-induced polyuria (Figure 236-1).[1] Even physiologic increases in cortisol inhibit basal vasopressin release in dogs.[2] Although much less pronounced than in the dog, also in humans with hyperadrenocorticism, there is decreased ability to concentrate urine. Interferences of glucocorticoids with vasopressin action, similar to those in dogs, have been reported in man.[3]

Figure 236-1 Relation of plasma vasopressin *(Pavp)* to plasma osmolality in nine dogs with pituitary-dependent hyperadrenocorticism (○) and six dogs with hyperadrenocorticism due to an adrencortical tumor (▪) during hypertonic saline infusion. The gray area represents the range in healthy dogs.[1] (Redrawn from Rijnberk A, editor: *Clinical endocrinology of dogs and cats,* Dordrecht/Boston, 1996, Kluwer Academic Publishers.)



236.2 PATHOGENESIS

Insufficient AVP release may be caused by defects at several functional sites in the chain of events that regulates discharge of the hormone into the blood. As a result, different forms of central diabetes insipidus can be distinguished. In dogs and cats only two forms have been recognized: complete and partial central diabetes insipidus. In the first type there is very little rise in urine osmolality with increasing plasma osmolality. These animals are essentially devoid of releasable AVP (Figure 236-2). In the second type AVP is released with increasing plasma osmolality but is subnormal in amount (Figure 236-3). In some cases this moderate AVP release only starts at rather high plasma osmolality values and therefore it may be said that not only is the secretory capacity limited but that there is also a high setting of the osmoreceptor.

1503

1504

Figure 236-2 The effect of water deprivation on body weight, plasma osmolality *(Posm)* and urine osmolality *(Uosm)* in a 4-year-old castrated male cat with a history of head trauma. The arrow represents an injection of aquous vasopressin (lysine-vasopressin, LVP). In this case the dehydration-induced rise in Posm did not lead to an increase in Uosm. This in combination with the sharp rise in Uosm following vasopressin administration justified the diagnosis of complete central diabetes insipidus. (Redrawn from Rijnberk A, editor: *Clinical endocrinology of dogs and cats,* Dordrecht/Boston, 1996, Kluwer Academic Publishers.)

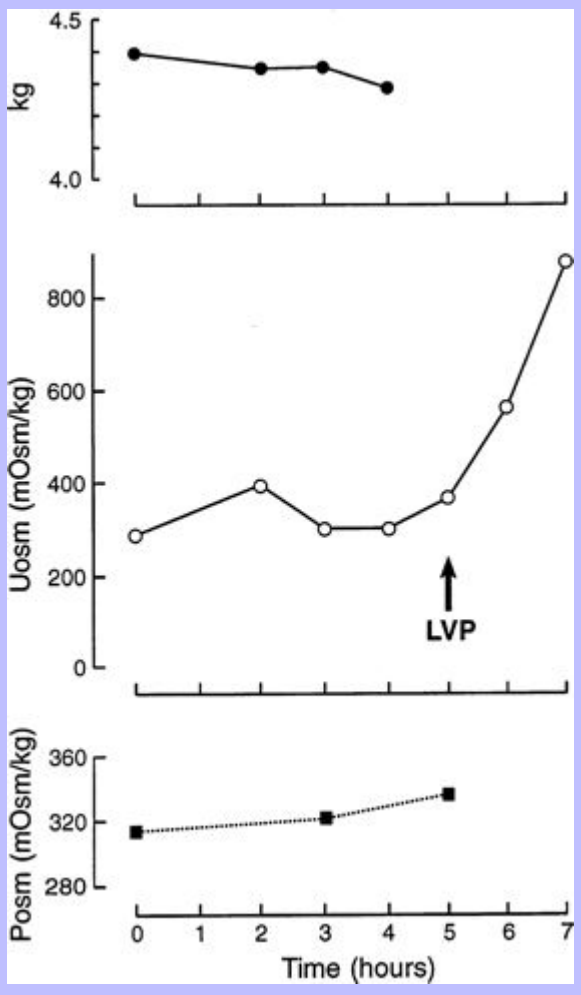


Figure 236-3 In a 5-month-old mongrel dog presented for polyuria, water deprivation led to a slow, subnormal rise in urine osmolality *(Uosm)*. At maximal Uosm, that is, when a "plateau" was reached, vasopressin (lysine-vasopressin, LVP) administration caused a 60% increase in urine osmolality. These observations are compatible with partial central diabetes insipidus. (Redrawn from Rijnberk A, editor: *Clinical endocrinology of dogs and cats,* Dordrecht/Boston, 1996, Kluwer Academic Publishers.)

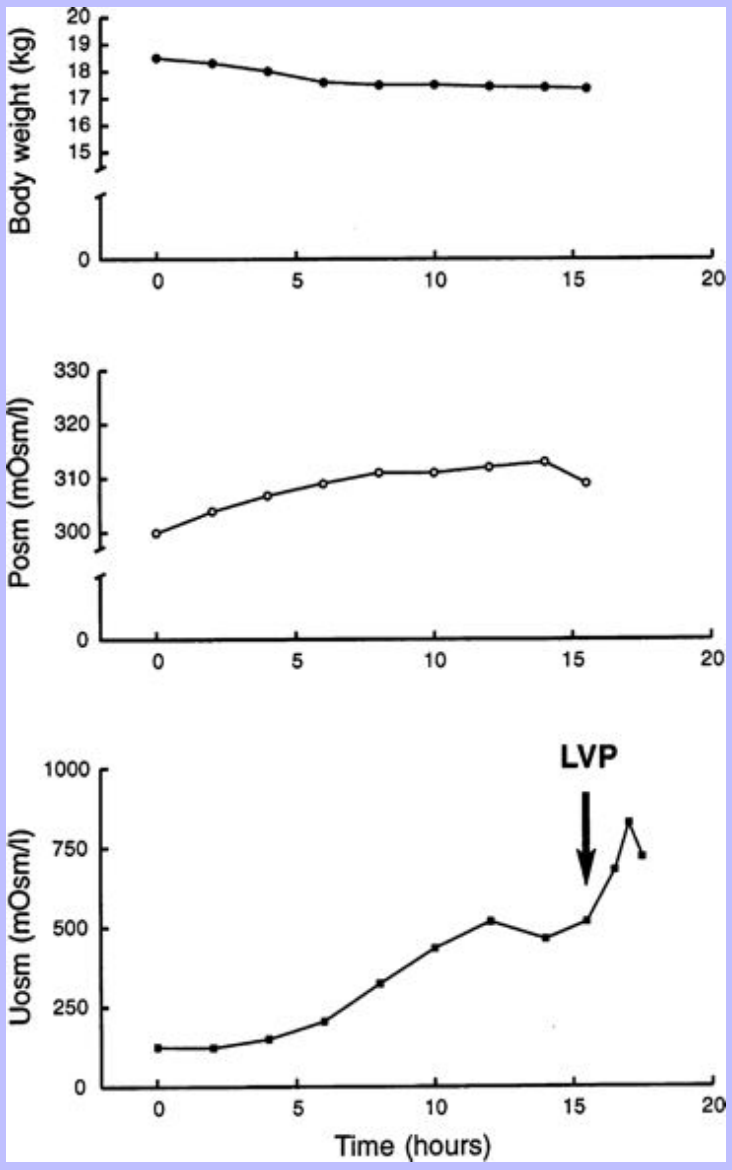

Among the lesions leading to impaired vasopressin release, an intracranial tumor is a likely cause in middle-aged and old animals. This is most often a primary pituitary neoplasm, but a craniopharyngioma or a meningioma may also be the causative lesion.[4–7] Metastatic lesions and inflammatory and parasitic lesions may also cause central diabetes insipidus.[8] Severe head injury, usually associated with fractures of the skull, is a rare cause in dogs and cats (see Figure 236-2); spontaneous remission may occur, probably because of regeneration of disrupted axons in the pituitary stalk.[9] There is also a report on a dog with evidence for the combination of anterior pituitary hormone deficiency and diabetes insipidus; in this case the pathogenetic significance of the head trauma at early age was unclear.[10]

An increasingly common cause of central diabetes insipidus is pituitary surgery.[11,12] The diabetes insipidus develops immediately after surgery and in the large majority of cases disappears spontaneously after periods of days to months. When the pituitary stalk is sectioned high enough to induce retrograde degeneration of the hypothalamic neurons, the central diabetes insipidus may be permanent. Finally, there is the possibility of the so-called idiopathic form. This term is used in cases of central diabetes insipidus in which no lesion in the hypothalamic and/or pituitary region can be demonstrated. This diagnosis is most common in young animals, although the course of the disease and/or the autopsy may eventually reveal a lesion that could not be identified initially.[13]

236.3 CLINICAL MANIFESTATIONS

The major manifestations are polyuria, polydipsia, and a near-continuous demand for water. These clinical signs may be sudden in onset and the maximum urine flow reached in 1 or 2 days. In severe cases water intake and urine volume may be immense and require micturition almost every hour throughout day and night. However, in the incomplete forms the urine volume may be only moderately increased. In the severe cases the enormous water intake may interfere with food intake and result in weight loss. Animals in which a large neoplasm is the underlying cause may have additional neurologic signs.

The urine concentration will be below that of plasma (specific gravity [SG] <1.010 and urine osmolality [Uosm] <290 mosmol/kg), but in the mild cases higher osmolalities (up to 600 mosmol/kg) may be found. Blood examination usually does not reveal abnormalities except for a slight hypernatremia due to commonly inadequate replenishment of the excreted water. When water is withheld from animals with the complete form of the disease, they develop within a few hours a life-threatening hypertonic encephalopathy (plasma sodium [PNa^+] > 170 mmol/l; Posm >375 mosmol/kg), initially characterized by ataxia and stupor. This situation may also be encountered when the causative lesion extends to the thirst center and adipsia develops.[14]

236.4 DIFFERENTIAL DIAGNOSIS

Apart from central diabetes insipidus there are in principal only two basic disorders that can account for the polyuria. These disorders are (1) primary polydipsia and (2) nephrogenic diabetes insipidus. Primary polydipsia is said to occur in hyperactive young dogs that are left alone during the day for many hours or have gone through significant changes in their environment. It has been observed that placing of the animal in a completely different environment may stop the problem. In these dogs during serial measurements urine osmolality spontaneously may reach values greater than 1000 mosm/kg. This finding can be regarded as diagnostic and precludes the need for a water deprivation test.[15]

Dogs fulfilling the commonly accepted criteria of primary polydipsia may exhibit abnormalities of vasopressin release. It is not clear whether these changes in vasopressin secretion are the result of the polydipsia and polyuria or may play a causative role.[15]

There are a few individual case reports of congenital nephrogenic diabetes insipidus, the condition in which the kidney tubules are insensitive to the action of antidiuretic hormone. Familial occurrence has been documented in huskies, in which the defect could be ascribed to a mutation affecting the affinity of the V_2 receptor for ligand.[16]

However, in addition to these two basic and infrequently encountered differential diagnoses, a wide variety of conditions cause polyuria. In the young animal this may be congenital kidney disease, whereas at all ages 1504
acquired kidney disease may lead to polyuria. Especially in the middle-aged and elderly animals endocrine 1505
conditions such as diabetes mellitus, hyperadrenocorticism, hyperaldosteronism[17], hyperthyroidism, pyometra, progestin-induced (luteal phase) growth-hormone excess[18], hyperparathyroidism, hypercalcemia of malignancy, tumor-associated polyuria[19], and the syndrome of inappropriate vasopressin secretion[20] have to be considered. In several of these conditions impaired release of vasopressin and/or interference with its action may play a role in the polyuria (see earlier and Figure 236-1). This has been documented for conditions such as hyperadrenocorticism, hepatoencephalopathy, and polycythemia.[1,21,22] In polycythemia it is likely that increased blood volume causes the impairment of vasopressin release. This range of possibilities may make it a difficult task to come to a diagnosis in an animal with polyuria. The algorithm presented in Figure 236-4 may be helpful.

236.5 DIAGNOSIS

Urine osmolality (161–2830 mOsm/kg) and urine specific gravity (1.006–>1.050) vary widely among healthy pet dogs.[23] In some dogs urine osmolality fluctuates considerably during the day and values close to plasma osmolality may be reached (Figure 236-5). There is experimental evidence that water consumption increases with food intake and exercise.[24] For example, with dry food, dogs consumed 40% of the total daily water intake during 2 hours after food intake. After treadmill running for 30 minutes water intake was higher than the water losses during the excercise.[24] However, it is unlikely that the sometimes strong fluctuations in urine osmolality of pet dogs during the day can be explained solely as an effect of feeding. There may be individual differences in early satiation of thirst, as mediated through oropharyngeal receptors.[23]

Apparently, in most pet dogs, low urine osmolalities are associated with sufficiently high urine osmolalities at other times of the day so that the owners do not perceive their dog to be polydipsic or polyuric. However, in other dogs the situation may be more pronounced and the animals are brought to the veterinarian because of polyuria and polydipsia.[23] Some of these animals may be recognized as having primary polydipsia (see above, section differential diagnosis). Therefore it is advisable to start the evaluation of dogs with polyuria by repeated measurements of urine osmolality and/or urine specific gravity during the day. As in humans, this approach may limit further clinical studies.[25]

The water deprivation test combined with vasopressin administration[26], as exemplified in Figures 236-2 and 236-3, is most commonly used for differentiation of the causes of polyuria. The test is difficult to perform correctly, unpleasant for the animal, relies heavily on the emptying of the bladder, and is indirect because changes in urinary concentration are used as an index of vasopressin release. Furthermore, the stimulus to

vasopressin release is a combination of hypertonicity and hypovolemia, especially towards the end of the period of dehydration.

Briefly the procedure is as follows: After 12 hours of fasting, water is withheld and plasma and urine are collected every hour or every 2 hours, depending on the severity of the polyuria. Osmolality is measured in both samples. At each collection, the animal is weighed. When the weight loss approaches 5% of initial body weight, the test should be stopped. When, in the presence of an adequate osmotic stimulus (Posm >305 mOsm/kg), urine concentration is maximal (less than 5% increase in Uosm between consecutive collections), (lysine) vasopressin or a vasopressin analogue such as DDAVP (see below) is administered.

In both nephrogenic diabetes insipidus and central diabetes insipidus Uosm will remain low during water deprivation. In complete diabetes insipidus Uosm will rise by 50% or more following the administration of vasopressin, whereas in the partial forms of central diabetes insipidus the rise will be greater or equal to 15%, and in nephrogenic diabetes insipidus there will be very little or no rise in Uosm (see Figures 236-2 and 236-3). Probably in part due to the indirect character of the test, the results may not always be conclusive.[27]

A more direct way to differentiate between the three basic causes of polyuria rests on the measurement of plasma vasopressin during osmotic stimulation by hypertonic saline infusion (Figures 236-1 and 236-6).[28] The euhydrated animal is infused for 2 hours through the jugular vein with 20% NaCl solution at a rate of 0.03 mL/kg body weight per minute. Samples for plasma (arginine) vasopressin (AVP) and plasma osmolality are obtained at 20-minute intervals. In the severely polyuric animal there is the risk of inducing critical hypertonicity. The test requires close observation of the animal and monitoring of plasma osmolality. This, and the fact that vasopressin is sensitive to proteolytic breakdown, make it advisable that the test is performed in institutions that have developed experience with the test.[29]

As in humans this approach can improve the diagnostic accuracy. The advantage is not in the severe forms of central diabetes insipidus, as in these conditions the standard indirect test will give a correct diagnosis. In all other categories of polyuria (i.e., in animals that concentrate their urine to various degrees during dehydration), the indirect test may be less reliable. Dogs in which the polyuria had initially been attributed to renal disease or to primary polydipsia proved to have partial central diabetes insipidus in the direct test. However, with regard to primary polydipsia some reservation in the interpretation is needed, as it has been demonstrated for humans that this chronic overhydration downregulates the release of AVP in response to hypertonicity.[28] As indicated above, also in dogs with so-called *primary polydipsia* there are indications for abnormalities in vasopressin release.[15]

The use of this direct approach has been limited so far, but it is worth considering in the few unresolved cases that remain after exclusion of the many other causes of polyuria (see Figure 236-4). It is often a question of whether the animal must endure for many years a life hampered by thirst, a large bladder, and unwanted behavior.

236.6 TREATMENT

As for almost all peptides, orally administered vasopressin is ineffective. Aquous (lysine) vasopressin may be administered subcutaneously in doses of 2 to 5 U. It will act for only about 3 hours. Nevertheless a good response has been reported in one dog, which received 5 U each 48 hours.[6]

The vasopressin analogue desmopressin, (DDAVP, 1-deamino, 9-D-arginine vasopressin)[*], provides antidiuretic activity for about 8 hours. One drop (1.5 to 4 µg) placed twice daily in the conjunctival sac sufficiently controls the polyuria in most dogs with central diabetes insipidus. With the administration of three drops a day the urine

production usually returns to normal, but some owners (in part for financial reasons) prefer to apply the drug only twice daily. In one report on a cat with partial diabetes insipidus the effect of conjunctivally administered desmopressin was described as poor, which might have been due to incorrect placement because of the cat's struggling.[30] With the injectable preparation (4 µg once a day or every 12 hours) of desmopressin the water consumption could be adequately controlled. The analogue can also be effective when administered as tablet: one-half tablet of 0.1 or 0.2 mg, two or three times per day, depending on the size of the animal and the effect.

Figure 236-4 In the first part of this algorithm the approach of the problem polyuria/polydipsia (pu/pd) is based upon the information from history. As a second step urinalysis has been introduced as it may happen that an animal presented with a seemingly convincing history of pu/pd has only pd because the owner has changed the food to dry food. As indicated in the text, it may be advisable at this stage to ask the owner for urine collections at 2-hour intervals. When the routine clinical chemistry has not revealed a specific suspicion, tests such as water deprivation and hypertonic saline infusion with AVP measurements may be needed. (Redrawn from Rijnberk A, editor: *Clinical endocrinology of dogs and cats,* Dordrecht/Boston, 1996, Kluwer Academic Publishers.)

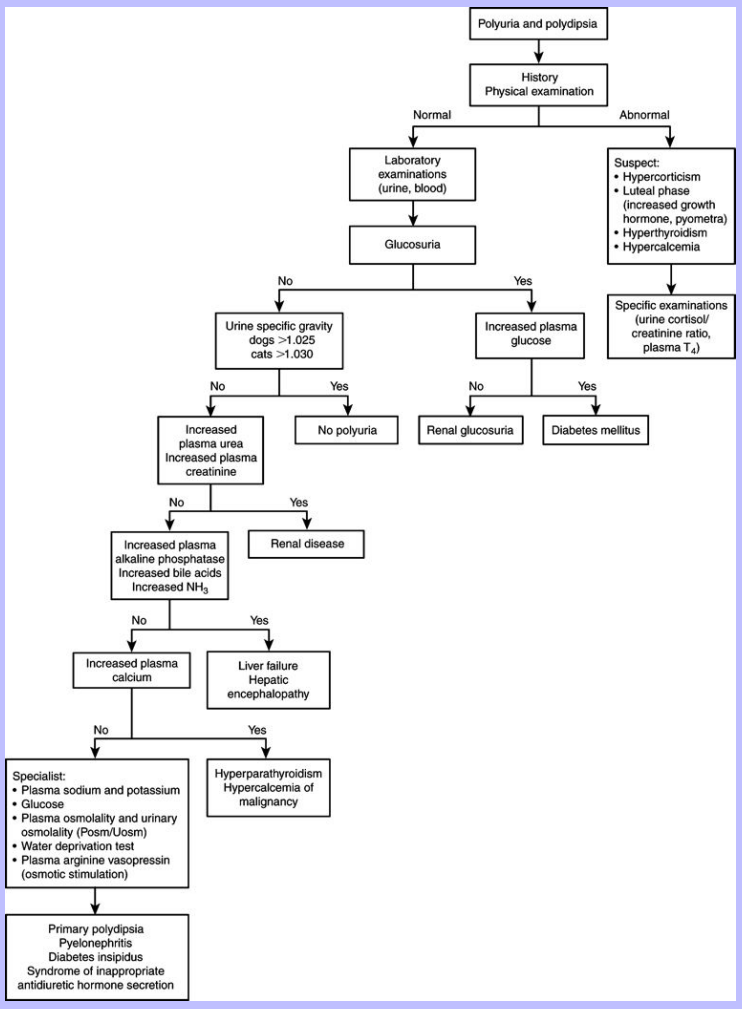

Figure 236-5 Fluctuation of Uosm during the day in a 9½-year-old castrated male Schnauzer (interrupted line) and a female 7½-year-old Belgian Shepherd (uninterrupted line). (Redrawn from Van Vonderen IK et al: Intra-and interindividual variation in urine osmolality and urine specific gravity in healthy pet dogs of various ages, J Vet Intern Med 11:30, 1997.)

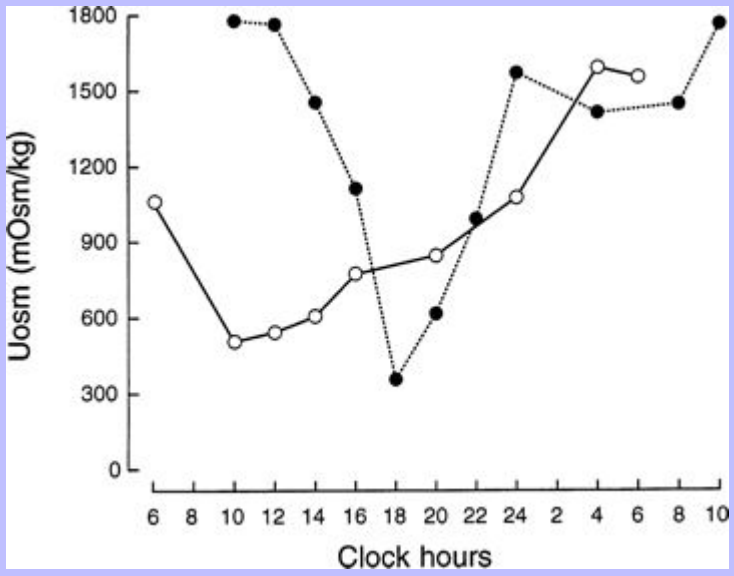

In dogs and cats undergoing hypophysectomy the administration of desmopressin is begun immediately after surgery. In healthy dogs this prevents hypernatremia.[31] In dogs hypophysectomized for pituitary-dependent hyperadrenocorticism mild hypernatremia may occur in the first 24 hours after surgery, despite prophylactic administration of desmopressin. This is probably related to the fact that in these dogs the hypercortisolism-induced vasopressin resistance is insufficiently compensated in the postoperative period by infusions and water intake.[11]

In cases of polyuria, in which all of the above mentioned differential diagnoses have been excluded, including central diabetes insipidus, the suspicion of nephrogenic diabetes insipidus may arise; a rare congenital disorder. Such cases have been treated with thiazide diuretics and a low-sodium diet. Oral administration of hydrochlorothiazide (2 to 4 mg/kg twice daily) and a low-sodium diet may decrease urine volume, albeit probably without significant change in urine osmolality. It is thought that the thiazide diuretic and the low sodium diet reduce plasma sodium concentration. This would decrease the stimulation of the thirst center and consequently the water intake. This may lead to extracellular volume contraction, a decreased glomerular filtration rate, increased proximal tubular sodium and water reabsorption, and decreased delivery of water to the distal tubule. The net effect is a reduction in urine volume.[32]

Figure 236-6 Relation of plasma vasopressin with plasma osmolality (Pavp) during hypertonic saline infusion in two dogs with central diabetes insipidus caused by pituitary tumor.[4] See also legend to Figure 236-1. (Redrawn from Rijnberk A, editor: *Clinical endocrinology of dogs and cats,* Dordrecht/Boston, 1996, Kluwer Academic Publishers.)

236.7 PROGNOSIS

In the absence of a neoplastic lesion the long-term prospects for cases with central diabetes insipidus are good. With appropriate treatment the animals become asymptomatic. Untreated animals with the complete form are always at risk of developing life-threatening dehydration when left without water for longer than a few hours. Animals with diabetes insipidus due to a pituitary tumor may lead acceptable lives for many months until the lesion has reached such size that neurologic signs develop.

237 CHAPTER • 237 Disorders of the Parathyroid Glands

Edward C. Feldman

The parathyroid glands and their production of parathyroid hormone (PTH) control serum calcium concentrations. Dogs and cats normally have four glands (two pairs). Two glands are anatomically closely associated with each thyroid lobe. Primary parathyroid gland disorders involve excess secretion of PTH (primary hyperparathyroidism [PHPTH]) or deficiencies of PTH secretion (primary hypoparathyroidism). Both conditions are relatively uncommon, but PHPTH is diagnosed at a much greater frequency than its counterpart. Further, hypercalcemia is diagnosed relatively frequently in dogs, and the first challenge for the veterinarian is appreciating the differential diagnosis for hypercalcemia and then diagnosing the specific condition causing this biochemical abnormality in an individual dog or cat (Box 237-1).

237.1 PRIMARY HYPERPARATHYROIDISM AND HYPERCALCEMIA IN DOGS

237.1.1 Cause

The essential disorder in PHPTH is the excessive synthesis and secretion of PTH by abnormal, autonomously functioning parathyroid "chief" cells.[1,2] The cause of this hormonal excess is usually a solitary parathyroid adenoma, but an adenoma of more than one gland, adenomatous hyperplasia of one or more parathyroid glands, and parathyroid carcinomas have been identified in both dogs and cats. By contrast, other forms of hyperparathyroidism (e.g., renal or nutritional secondary hyperparathyroidism) are usually the result of nonendocrine alterations in calcium and phosphorus homeostasis. Such disturbances indirectly affect the parathyroid glands, causing diffuse hyperplasia. However, in these conditions the secretion of PTH is not autonomous. The "hyperplasia" occasionally diagnosed in the primary condition (PHPTH) is a condition associated with autonomous secretion of PTH. Therefore histologic descriptions may not indicate primary autonomous from secondary secretory patterns. Depending on cause, serum calcium concentrations in secondary disorders may range from low to normal to increased. PHPTH is virtually always associated with hypercalcemia.

237.1.1.1 Box • 237-1 Differential Diagnosis of Hypercalcemia

237.1.1.1.1 Common

Lymphosarcoma

Hypoadrenocorticism

Primary Hyperparathyroidism

Chronic renal failure

237.1.1.1.2 Uncommon

Apocrine gland carcinoma of the anal sac

Multiple myeloma

Vitamin D toxicosis

237.1.1.1.3 Uncommon to Rare

Spurious

Hemoconcentration

Carcinomas:

lung, mammary, nasal, pancreas, testicle, thymus, thyroid, vagina

Acute renal failure

Nutritional secondary hyperparathyroidism

Granulomatous disease blastomycosis, histoplasmosis, schistosomiasis

237.1.2 Pathophysiology

237.1.2.1 Calcium-Parathyroid Hormone Feedback System

Serum calcium is the major factor in regulation of PTH secretion. In normal animals, an inverse linear relationship exists between serum calcium and PTH concentrations.[3] In other words, as calcium concentrations in the serum decrease, PTH secretion is stimulated to maintain serum calcium concentrations at some specific level. The system functions as if there were a "calciostat" that operates at a serum calcium concentration set point of about 10.5 to 11.5 mg/dL. When serum calcium concentrations decrease below these levels, the rate of PTH secretion increases; when the serum calcium concentration exceeds the set point (as might occur after intake of a high-calcium meal), PTH secretion is suppressed. In PHPTH, normal negative-feedback homeostatic control is lost, and PTH secretion becomes chronically increased. This appearance of "autonomous" secretion may be a change in the "set point." The autonomous secretion of PTH is not suppressible by the increased concentration of calcium perfusing the parathyroid glands. Conversely, in secondary hyperparathyroidism, secretion by the parathyroid glands is normally suppressible by increased concentrations of calcium.

237.1.2.2 Severe Hypercalcemia

Hypercalcemia develops when the entry of calcium into the extracellular fluid (regardless of the source) overwhelms mechanisms that maintain normocalcemia. One such mechanism is suppressed secretion of PTH, a process obviously negated when the cause of hypercalcemia is autonomous secretion of PTH or a molecule with similar biologic activity. In cancer-associated hypercalcemia, the secretion of PTH is suppressed, but the humoral factor that activates osteoclasts is the autonomous secretion of a parathyroid hormone–related protein (PTHrP). PTHrP is a protein with a structure and biologic activity quite similar to that of PTH.[4,5]

In the setting of accelerated bone resorption, the kidney is the principal defense against hypercalcemia.[6] When renal and endocrine function is normal, any tendency for a rise in serum calcium is attenuated by increased urinary excretion of calcium. This process is inhibited by PTH in PHPTH or by PTHrP in hypercalcemia of malignancy. These hormones induce osteoclast-mediated bone resorption, intestinal absorption of calcium, and renal tubular reabsorption of calcium.[7] This impairs the ability of the kidneys to excrete the increased filtered load of calcium. Thus animals with an excess of PTH lack the first lines of defense against hypercalcemia. The hypercalcemic state also interferes with renal mechanisms for reabsorption of sodium and water, leading to polyuria. This is due to an acquired inability to respond to antidiuretic hormone (ADH)—in essence, a reversible form of nephrogenic diabetes insipidus. In PHPTH, hypercalcemia is enhanced by the increased production of vitamin D and by a decrease in the amount of serum phosphate available to form complexes with serum ionized calcium. The result is a decreased tubular reabsorption of phosphate, hyperphosphaturia, and hypophosphatemia. These actions are responsible for the development of the biochemical triad classic for PHPTH: hypercalcemia, hypophosphatemia, and hyperphosphaturia.

1508 1509

237.1.3 Signalment

237.1.3.1 Age and Gender

PHPTH is typically diagnosed in older dogs and appears to be much less common, or at least less frequently diagnosed, in cats. The mean age of the 187 dogs with PHPTH seen at our hospital is 11.2 years, with a range of 4 to 17 years (Figure 237-1). More than 95% of the dogs are 7 years of age or older. No apparent sex predilection exists.

237.1.3.2 Breed

Reliable information regarding breed predisposition for any disorder requires sophisticated epidemiologic evaluation. To the author's knowledge, such an investigation has not been undertaken with respect to canine PHPTH. Regardless, it is reasonable to point out that the Keeshond is far from being the most popular breed of dog, as opposed to poodles, German shepherds, retrievers, and the like. In spite of this relative lack of popularity, 48 of the 187 dogs (26%) in our series have been Keeshonden. The other breeds represented three or more times in series include Labrador retrievers, German shepherd dogs, Cocker spaniels, golden retrievers, springer spaniels, Shih Tzu, poodles, Australian shepherds, Rhodesian ridgebacks, Doberman pinschers, and mixed breed dogs (Table 237-1). Several of these breeds, however, are simply popular. Whether or not breed predispositions exist awaits epidemiologic evaluation. However, two points should be made. First, the Keeshond is over-represented; second, dogs of any breed or mixed breeding and any age from 4 years of age and older can be afflicted by this condition.

Figure 237-1 Age distribution of 78 dogs with primary hyperparathyroidism. The mean age at the time of diagnosis was 10.5 years. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders Co, 2004.)

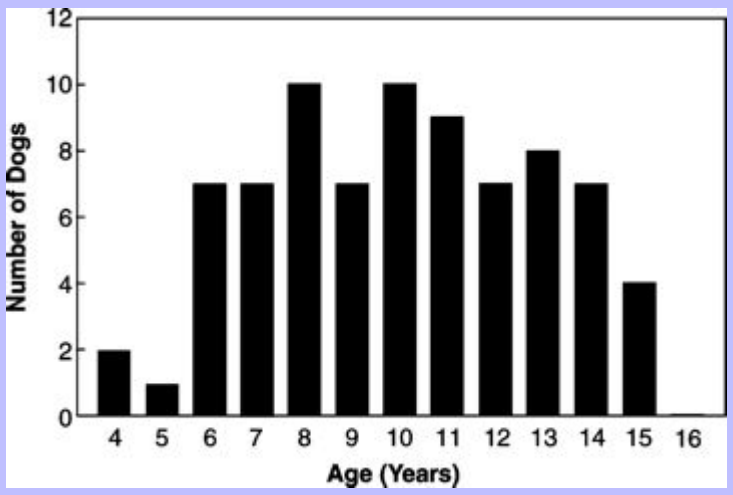

Table • 237-1 Breed Distribution of 187 Dogs with Primary Hyperparathyroidism

BREED	NUMBER OF DOGS	PERCENT OF DOGS
Keeshond	48	26%
Labrador retriever	18	10%
Cocker spaniel	14	7%
German shepherd dog	14	7%
Golden retriever	12	6%
Springer spaniel	9	5%
Standard poodle	8	4%
Shih Tzu	8	4%
Australian shepherd	7	4%
Rhodesian ridgeback	6	3%
Doberman pinscher	6	3%

237.1.3.3 Hereditary Disease

Hereditary neonatal PHPTH was reported in two German shepherd dogs.[8] The incidence of this syndrome in puppies and young dogs must be quite rare because no other report of neonatal disease has appeared in the literature. Our series of dogs with PHPTH does not include any less than 4 years of age.

237.1.4 Anamnesis: Clinical Signs

237.1.4.1 General

Clinical signs due solely to hypercalcemia, when observed by an owner, are mild in most dogs.[9] The only condition that has hypercalcemia as the sole problem is PHPTH. The most common signs associated with PHPTH include polyuria, polydipsia, decreases in appetite, decreases in body weight, decreased activity (muscle weakness?), and signs related to stones or infection within the urinary tract. Other signs reported secondary to hypercalcemia include the gastrointestinal (GI) signs of anorexia, vomiting, constipation, and, rarely, pancreatitis. Signs associated with the central nervous system (CNS) include mental dullness, obtundation, and even coma. One dog with PHPTH had ataxia and circling that resolved after resolution of the PHPTH. Again, clinical signs in dogs with PHPTH are almost always mild or not noticed. When a dog with hypercalcemia has worrisome signs, it almost always has a disease other than PHPTH. These worrisome signs therefore are almost always associated with the underlying cause for the hypercalcemia (e.g., cancer, renal failure, hypoadrenocorticism, toxin).

The mildest form of PHPTH may not be associated with any signs, and the hypercalcemia is identified serendipitously only after a standard biochemical panel has been obtained and reviewed. This is certainly true in humans, in whom *occult* primary hyperparathyroidism is more prevalent than the symptomatic form of the disorder.[10–13] When clinical signs in dogs do develop, they initially tend to be mild, insidious, and nonspecific. Most owners are unaware of specific clinical signs. It is not until their pet has been treated for PHPTH that owners, retrospectively, realize that their dog had signs. It is this concept that resulted in an editorial suggesting that all people with PHPTH be treated, because they may appreciate their illness that 1509
they have been ill until their disease has been resolved.[14] In our series of dogs with PHPTH, 35% had 1510
clinical signs related to PHPTH for more than 6 months and *all*, either retrospectively or prospectively, had signs for at least 1 month (Table 237-2). The clinical signs attributable to PHPTH and hypercalcemia usually involve one, two, or all three of these organ systems: renal, GI, or neuromuscular (Table 237-3).

Table • 237-2 Duration of Clinical Signs in 168 Dogs with Naturally Occurring Primary Hyperparathyroidism

DURATION (MONTHS)	PERCENT OF DOGS
<1	19%
1–3	20%
3–6	19%
6–12	24%
>12	18%

237.1.4.2 Renal: Kidneys, Bladder, and Urethra

237.1.4.2.1 Polydipsia, polyuria, or both

The most common clinical signs in dogs with PHPTH (152 of 187 dogs; 81%) are polyuria, polydipsia, and urinary incontinence (see Table 237-3). These signs are a result of impaired renal tubular response to ADH and impaired renal tubular resorption of sodium and chloride. Together, these alterations account for a significant increase in urine volume and are a direct result of hypercalcemia. This acquired and

reversible form of nephrogenic diabetes insipidus causes the production of relatively dilute, solute-free urine. Compensatory polydipsia develops to maintain normovolemia. Surprisingly, the polydipsia and polyuria either are not observed or are thought to be mild by most owners but are obvious on review of randomly obtained urine specific gravities (USGs). These specific gravities were much more dilute than would have been expected from owner comments. Of 187 dogs with PHPTH, 46 (24%) had USGs of 1.001 to 1.007; 69 dogs (38%) had USGs that were in the isosthenuric range of 1.008 to 1.012; 60 dogs (32%) had USGs of 1.013 to 1.020; only eight had values of 1.021 to 1.030 and 4 greater than 1.030. Thus 94% of dogs with PHPTH had USGs less than or equal to 1.020 (Table 237-4).

Table • 237-3 Frequency of Clinical Signs Reported in 168 Dogs with Naturally Occurring Primary Hyperparathyroidism

SIGN	PERCENT OF DOGS
Polyuria/polydipsia (PU/PD)	81%
Listlessness	53%
Incontinence	47%
Weakness, exercise intolerance	47%
Inappetence	37%
Urinary tract signs (straining, blood, frequency)	29%
Muscle wasting	17%
Vomiting	12%
Shivering	10%
Constipation	6%
Stiff gait	5%

237.1.4.2.2 Urinary tract calculi or infection

1510

1511

Another of the more common causes for owner concern in dogs with PHPTH was observation of clinical signs consistent with urinary tract infection, calculi, or both. These signs included frequency, urgency, incontinence, hematuria, stranguria, or apparent urinary obstruction. At some time in the year preceding diagnosis, 123 of 168 owners (73%) had seen at least one of these clinical signs in their dogs. Sixty-one of 187 (33%) PHPTH dogs had uroliths, and 46 dogs (24%) had a urinary tract infection at the time of diagnosis.

237.1.4.3 Listlessness, Depression, and Decreased Activity

Listlessness or decreases in activity were observed in 99 (53%) of 187 dogs with PHPTH. Increased serum calcium concentrations depress the excitability of central and peripheral nervous tissue, which may be responsible for this clinical manifestation. Alternatively, these clinical signs may be a reflection of muscle weakness. Humans with this disorder may exhibit nonspecific neurologic abnormalities that include impaired mentation, mental depression, hypoactive deep tendon reflexes, and loss of pain perception.[13]

237.1.4.4 Weakness and Muscle Wasting

Weakness or exercise intolerance was observed in 88 (47%) of 187 dogs with PHPTH. Increased serum calcium concentrations decrease cell membrane permeability in nervous and muscular tissue. In addition, skeletal muscle weakness, primarily of the proximal muscle groups, may result from a primary neuropathy that ultimately causes muscle atrophy. Muscle wasting and weight loss were observed in 32 (17%) of the 187 dogs.

237.1.4.5 Inappetence

Owners observed some degree of reduced appetite in 69 (37%) of 187 dogs with PHPTH. This problem probably developed as a result of hypercalcemia-induced decreased excitability of GI smooth muscle or from direct effects on the CNS. Gastric ulcers, noted in some hypercalcemic people, has not been observed in dogs with PHPTH. Only one dog had concurrent pancreatitis. One common assumption is that hypercalcemia would induce secondary renal failure and tertiary loss of appetite. However, this is quite uncommon.

237.1.4.6 Shivering, Twitching, and Seizures

Shivering and muscle twitching have been observed in hypercalcemic dogs, and seizure activity has been reported in a dog with PHPTH.[15] These signs might result from cerebral microthrombi, vasospasm, or other conditions.

237.1.5 Physical Examination

A thorough physical examination is imperative in any animal with documented hypercalcemia. Physical examinations are usually unremarkable in dogs with PHPTH. When abnormalities exist, they are typically related to the presence of uroliths. Other abnormalities (weakness, muscle atrophy) are usually subtle or

nonspecific. Although parathyroid gland tumors are not palpable dogs with PHPTH, tumors have been palpable in four of ten cats with this condition. The most common cause of hypercalcemia in dogs is hypercalcemia of malignancy (Box 237-1). Lymphosarcoma, apocrine gland carcinoma of the anal sac, mammary gland adenocarcinoma, vaginal sarcoma, and multiple myeloma are among cancers capable of causing hypercalcemia that may be identified on examination. The diagnostic approach to a dog with confirmed hypercalcemia is to rule out the presence of malignancy before pursuing the diagnosis of PHPTH (see Figure 237-2). Non-neoplastic causes of hypercalcemia may be suspected after a thorough physical examination. For example, in renal failure, the kidneys may be palpably abnormal. Dogs with Addison's disease may have bradycardia, weak femoral pulses, melena, or a bloody rectal discharge.

237.1.6 Clinical Pathology: Hemogram, Serum Biochemical Profile, and Urinalysis

No typical hemogram abnormalities have been identified in dogs with PHPTH.

237.1.6.1 Serum Total Calcium Concentration

237.1.6.1.1 Results in dogs and humans

Hypercalcemia is the hallmark abnormality of PHPTH (Figure 237-3). The mean serum calcium concentration in 187 dogs with PHPTH was 15.3 mg/dL, with a range of 12.1 to 23.0 mg/dL (Table 237-5). This mean value could be arbitrarily inflated because evaluation of hypercalcemia is limited to those animals with serum calcium concentrations greater than 12.0 mg/dL (the upper reference range limit is 11.7 mg/dL). In most dogs, hypercalcemia was initially identified by a referring veterinarian on at least two occasions and then rechecked several times after referral. Of PHPTH dogs, 102 of 187 (55%) had an initial total serum calcium concentration of 12 to 14 mg/dL; 58 (31%) had an initial concentration of 14 to 16 mg/dL; 18 (9%) had an initial concentration of 16 to 18 mg/dL; and nine (5%) had an initial concentration of greater than 18 mg/dL (range of 18 to 23 mg/dL). Of these latter nine dogs with severe hypercalcemia, it is of interest to mention that their mean blood urea nitrogen (BUN) concentration was 22 mg/dL, with only one dog having a BUN above the reference range limit of 28 mg/dL.

Although it is assumed that untreated PHPTH will result in progressively increasing serum calcium concentrations, this has not been the experience in people. A group of 60 “asymptomatic” PHPTH people was not treated for 10 years. Their mean total serum calcium concentration, at the time of diagnosis, was 10.5 mg/dL (reference range 8.4 to 10.2 mg/dL), 5 years later it was 10.6, and a total of 10 years after diagnosis it was 10.3 mg/dL.[13] However, eight developed uroliths during the decade, leaving 52 who remained asymptomatic. Our experience with dogs suggest that hypercalcemia associated with PHPTH remains static or slowly increases with time.

237.1.6.1.2 Factors affecting serum calcium concentration

Marked lipemia can falsely increase total calcium values determined by some automated analyzers. Hemoconcentration (dehydration) can cause mild hypercalcemia (typically < 13 mg/dL). Hemolysis can also falsely increase the total serum calcium concentration measured with an automated analyzer. Young animals may have mild increases in serum calcium concentration, and postprandial samples may yield false increases. Excess use of oral phosphate binders may cause the serum calcium concentration to increase. Ethylenediamine tetra-acetic acid (EDTA) increases calcium values determined by atomic absorption spectrophotometry and decreases results obtained with other methods. Collecting and storing

samples in glassware or plastic containers that have been washed with detergents or exposed to chalk may increase calcium results and also cause spurious values for other electrolytes. Acidosis may decrease plasma protein-binding affinity for calcium and increase ionic calcium concentrations, creating mild physiologic hypercalcemia.

237.1.6.1.3 Plasma protein concentrations

Calcium in plasma or serum exists in three forms or fractions: ionized (free calcium), complexed or chelated (bound to phosphate, bicarbonate, sulfate, citrate, and lactate), and protein bound. In clinically normal dogs, protein-bound, complexed, and ionized calcium account for approximately 34%, 10%, and 56% of the total serum calcium, respectively.[16,17] Laboratories generally measure these components together and report them as a *total* calcium value. Ionized calcium is the biologically active component, and the protein-bound calcium serves as a "reservoir" or storage pool for the ionized fraction. However, changes in serum concentration of albumin and globulins may alter the measured *total* serum calcium concentration without altering ionized calcium levels. Despite an alteration in the total amount of plasma calcium resulting from hyperproteinemia or hypoproteinemia, the biologically active *ionized* calcium concentration usually remains within reference limits.

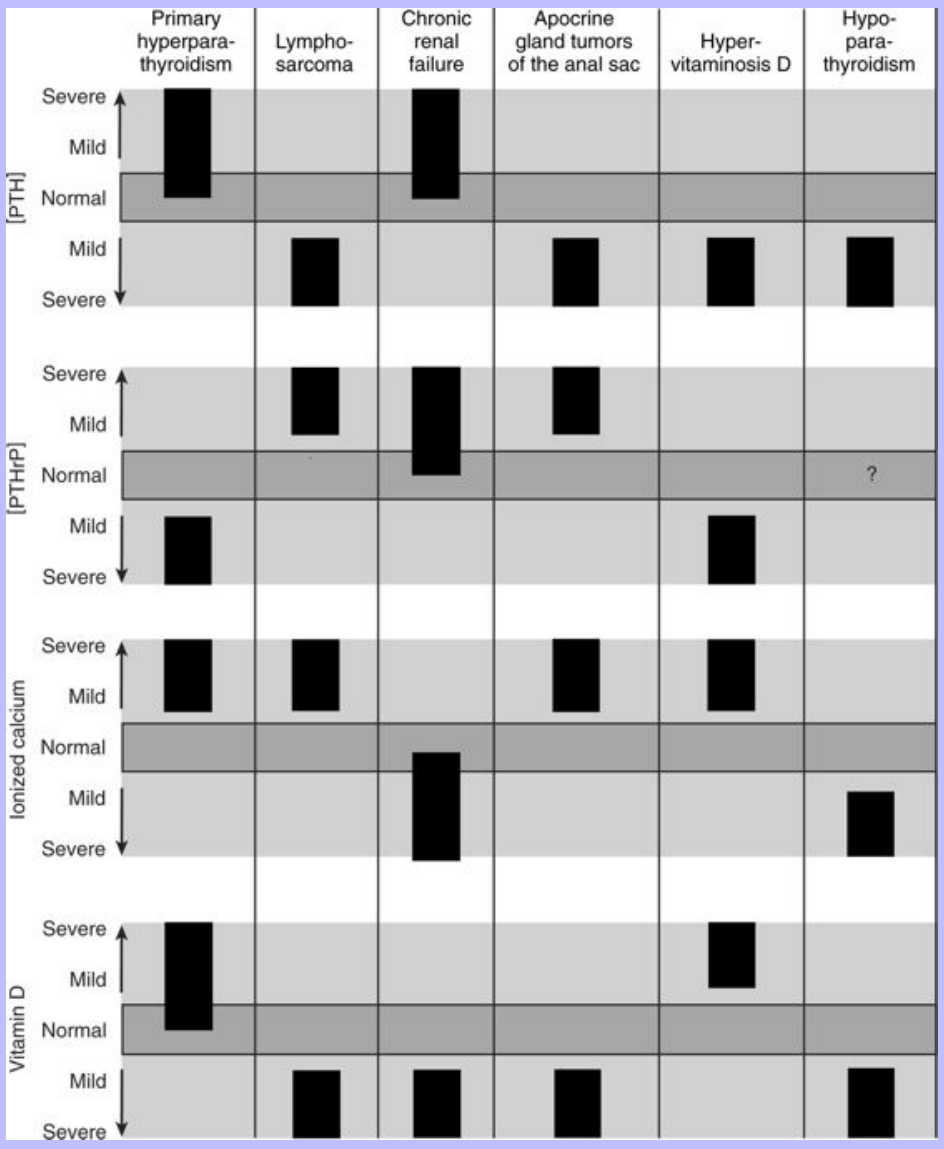
Figure 237-3 Graph showing the serum parathyroid hormone (PTH), parathyroid hormone-related peptide (PTHrP), ionized calcium, and vitamin D concentrations in the most common causes for hypercalcemia of dogs. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders Co, 2004.)



Two formulas were developed for use in dogs to account for changes in the reported serum calcium value attributed to changes in serum protein values.[18] The formulas were of significant value prior to routine availability of ionized calcium assays. These formulas are:

$$\text{Corrected Total Ca (mg/dL)} = \text{Measured Total Ca (mg/dL)} - \text{albumin (g/dL)} + 3.5$$

or

$$\text{Corrected total Ca (mg/dL)} = \text{Measured total Ca (mg/dL)} - [0.4 \times \text{total protein (g/dL)}] + 3.3$$

Hypoalbuminemia is a common explanation for apparent hypocalcemia. However, this "hypocalcemia" usually causes no clinical signs and is associated with only mild changes from reference ranges. Although correction to normal limits implies that the ionized fraction is normal, the ionized fraction may yet be low. These formulas, developed more than 2 decades ago, were derived from serum albumin concentration results obtained with analytical methods no longer used by modern automated analyzers. At the time, a positive correlation was noted, but only 33% of the variability in serum total calcium concentration could be attributed to serum albumin concentration, and only 17% of the variability could be attributed to serum total protein. There was no association in cats between serum total protein and serum calcium concentrations, and only 18% of the variability in total calcium concentration could be attributed to albumin concentration.[19] In another study, only 17% and 29% of the variability in total serum calcium concentration in dogs and cats, respectively, could be attributed to serum albumin concentration.[20] For these reasons, use of these correction formulas are not recommended.[21]

237.1.6.2 Serum Ionized Calcium Concentration

The ionized fraction of total circulating calcium concentration is the biologically active form. This information (together with the increasing availability of valid assays for ionized calcium and realization that dogs with chronic renal failure tend to have normal to low ionized concentrations versus the increased concentrations in other hypercalcemic conditions) has created a growing interest in results of this parameter in hyper- and hypocalcemic dogs. The mean ionized calcium concentration on initial blood samples in 136 dogs with PHPTH was 1.86 mmol/L, with a range of 1.22 to 2.29 mmol/L (reference range 1.12 to 1.42 mmol/L; see Table 237-5). Nine of the 136 dogs (7%) had a serum ionized calcium concentration within the referee range; 37 (27%) had results of 1.43 to 1.65 mmol/L; 64 (47%) had concentrations of 1.66 to 1.9 mmol/L, and 26 (19%) had concentrations greater than 1.9 mmol/L. In general, there was good correlation between serum total and ionized calcium results. However, no dog with PHPTH had a total calcium concentration within the reference range, whereas 7% had ionized calciums within the reference range. It is suspected that these ionized calcium concentrations within the reference range are the result of external (in vitro) factors (aerobic collection, pH).

237.1.6.3 Serum Phosphorus Concentration

Low or low-normal serum phosphorus concentrations (< 4.0 mg/dL) are typical of PHPTH (see Figure 237-3). Hypophosphatemia is the result of PTH-induced inhibition of renal tubular phosphorus resorption, resulting in excessive urinary loss. In 187 dogs with PHPTH, the mean serum phosphorus concentration was 2.8 mg/dL (< the lower limit of the reference range; 3.0 to 6.2 mg/dL), with a range of 1.5 to 6.8 mg/dL (see Table 237-4). Twenty of 187 dogs (11%) had serum phosphate concentrations less than 2.0 mg/dL; 99 (53%) had results of 2.0 to 2.9 mg/dL; 50 (27%) had results in the low normal range of 3.0 to 3.9 mg/dL; 12 (6%) had values in the mid-normal range of 4.0 to 4.9; 4 (3%) had values 5.0 mg/dL and only one of those four dogs had a serum phosphate concentration above reference limits (6.8 mg/dL). As a point of interest, nine of the 187 dogs had BUN values above the reference limit of 28 mg/dL. Of those nine dogs, eight had serum phosphate concentrations within the reference range.

The serum phosphorus concentration should always be evaluated relative to the serum calcium concentration and renal function. Hypophosphatemia, when dietary phosphate is adequate and when oral phosphate-binding agents are not being given, is consistent with either PHPTH or hypercalcemia of malignancy (see Figure 237-3). Other causes for hypophosphatemia are less common (Box 237-2). Hyperphosphatemia in the absence of azotemia suggests a nonparathyroid cause for hypercalcemia. When both hyperphosphatemia and azotemia are present, the clinician must rely on the history, physical examination, and other diagnostic tests to determine if the primary problem is hypercalcemia with secondary renal failure (rare) or renal failure with secondary hypercalcemia (common). Determination of the serum ionized calcium concentration can be of value. Dogs with renal failure and increases in total serum calcium concentration usually have ionized calcium concentrations that are normal or mildly decreased, dogs with PHPTH have increases in both fractions.

237.1.6.4 Blood Urea Nitrogen and Serum Creatinine Concentration

BUN (mean: 17 mg/dL) and serum creatinine concentrations (mean: 1.0 mg/dL) are usually within reference limits in dogs with PHPTH (see Table 237-4). Nine dogs (5%) had BUN concentrations less than 10 mg/dL; 112 (60%) had values of 10 to 17 mg/dL; 39 (21%) were 18 to 22 mg/dL; 18 (10%) were 23 to 28 mg/dL; 8 (4%) were 29 to 47 mg/dL, and one dog had a value of 92 mg/dL. Four of the nine dogs with

an abnormal BUN had a serum creatinine concentration within the reference range. The two highest serum creatinine concentrations were 2.3 and 4.1, respectively. This is most impressive when considering the mean age of these dogs (11.2 years). The literature strongly suggests that hypercalcemia, especially when chronic, may damage kidneys. However, it would appear that dogs with PHPTH are protected from renal damage, whether this protective effect is due to the low calcium × phosphate product or some other factor.

237.1.6.5 ## Urinalysis

The mean USG in 187 dogs with PHPTH was 1.011. Forty-six dogs (24%) had a USG on initial evaluation less than 1.008; 69 (38%) had specific gravities of 1.008 to 1.012; 60 (32%) had values of 1.013 to 1.020; eight (4%) had results of 1.021 to 1.030; and four had concentrations greater than 1.030 (see Table 237-4). Hypercalcemia interferes with ADH action and thereby causes a reversible form of nephrogenic diabetes insipidus. Isosthenuria (or hyposthenuria) may develop from *any* cause of hypercalcemia. Thus the combination of hypercalcemia and dilute urine is considered a "cause-and-effect" phenomenon but is not specific.

237.1.6.6 Urine Sediment

Hematuria, pyuria, bacteriuria, and crystalluria are identified frequently on urine sediment examination from dogs with PHPTH. Fifty-nine of 187 PHPTH dogs (31%) either had a history of uroliths removed by referring veterinarians within the 12 months preceding examination or were identified as having uroliths with radiographs or ultrasonography at the time of initial evaluation at our hospital. Urinary tract infection had been present or was present on initial examination at the author's hospital in 46 of 187 dogs with PHPTH (24%).

237.1.7 Electrocardiography

Experimentally induced hypercalcemia may increase myocardial contractility, shorten mechanical ventricular systole, and decrease myocardial automaticity. Potential electrocardiographic changes caused by hypercalcemia include a prolongation of the P-R interval and a shortening of the Q-T interval due to a shortened S-T segment. Theoretically, decreases in myocardial conduction velocity and shortened refractory periods could predispose the heart to arrhythmias. However, dogs with PHPTH rarely have abnormalities on electrocardiogram.

237.1.8 Radiology

237.1.8.1 Thoracic Radiographs

The major purpose of evaluating radiographs in the hypercalcemic dog or cat is to identify abnormalities that would help establish a cause. The anterior mediastinum, perihilar, and sternal lymph nodes should be evaluated for a mass or lymphadenopathy. Dogs with hypercalcemia secondary to lymphosarcoma may have a mediastinal mass. The ribs, vertebrae, and any long bones included in the film can be evaluated for osteolytic areas due to myeloma or other metastatic tumors. Lung fields should be assessed for possible masses that might represent primary or metastatic lesions.

237.1.8.2 Abdomen and Skeleton

The sublumbar area and mesenteric lymph nodes can be evaluated for enlargements that would support metastatic apocrine gland carcinomas of the anal sac or lymphoma. The liver and spleen can be evaluated for enlargement or irregularities associated with lymphoma. Other than calculi within the urinary system, radiographic abnormalities are not associated with PHPTH.

237.1.9 Ultrasonography

237.1.9.1 Neck

With continuing improvement in equipment and experience, normal parathyroid glands are now routinely visualized with ultrasonography in dogs.[22] Parathyroid nodules from dogs with PHPTH have been measured to be as small as 2 mm in diameter and as large as 23 mm in diameter. Most adenomas are 4 to 9 mm in diameter and are easily visualized.[23,24] One recent study demonstrated a statistically significant difference in lesion size, comparing hyperplastic parathyroid glands (2 to 6 mm, mean 2.9 mm) to parathyroid adenomas and adenocarcinomas (4 to 20 mm, mean 7.5 mm).[25]

Radiologists have evaluated the cervical area of 98 dogs in our series with confirmed PHPTH. Virtually all these dogs had one or more parathyroid gland (masses) visualized. Eleven of the 98 dogs had two parathyroid nodules each. Thus 109 nodules were identified in the 98 dogs. Sixty-five of 109 parathyroid masses (60%) were 3 to 6 mm in diameter; 29 (27%) were 7 to 10 mm in diameter; nine (8%) were 11 to 15 mm in diameter; and six (5%) were 16 to 23 mm in diameter (see Table 237-5; Figure 237-4). No dog had more than two parathyroid masses identified. Parathyroid masses are usually round or oval, well marginated, and hypoechoic to anechoic compared with surrounding thyroid gland parenchyma (Figure 237-4). However, not every parathyroid nodule is obvious. It is occasionally difficult to distinguish large parathyroid masses from thyroid. Another important issue that must be stressed, is the subjective nature of this tool. In one of our studies, experienced radiologists correctly identified a solitary parathyroid mass in 11 of 11 dogs and two parathyroid masses in another. However, less experienced radiologists identified a parathyroid mass in only four of seven dogs.[26]

The accuracy of cervical ultrasonography in dogs with PHPTH has been similar to that reported in humans: 90% to 95% of parathyroid adenomas and a smaller percentage of hyperplastic parathyroid glands can be visualized.[27] Experienced radiologists identify parathyroid masses with ultrasonography more consistently than surgeons during surgery because of the occasional parathyroid mass located within a thyroid lobe that is neither visible nor palpable to the surgeon. Therefore cervical ultrasonography is potentially an extremely valuable diagnostic aid.

237.1.9.2 Abdomen

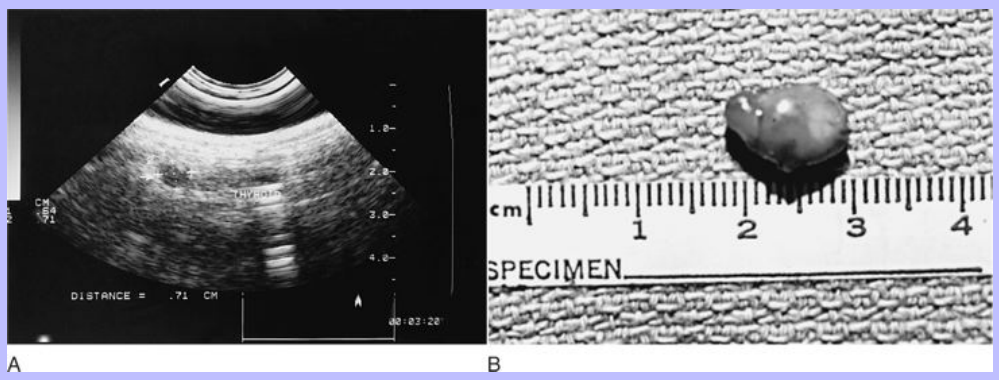
Ultrasonic scanning of the abdomen should also be a routine component of the diagnostic evaluation of hypercalcemic dogs and cats. If the liver, spleen, mesenteric lymph nodes, or other abdominal structures appear abnormal, percutaneous biopsy of that structure should be strongly considered. Ultrasonography has been an excellent tool for identifying uroliths as well. Most are seen within the bladder, but renal, ureter, and urethral stones have also been visualized.

237.1.10 Assays: PTH, PTHrP, Vitamin D (Calcitriol)

Dogs with PHPTH usually have serum PTH concentrations that range from within the reference range to being exceedingly increased (see Table 237-5 and Figure 237-3; Figure 237-5). In addition, serum PTHrP concentrations are usually undetectable, whereas calcitriol concentrations (not usually tested) would be normal to increased.[28] Serum PTH concentrations must always be evaluated in the context of the serum calcium

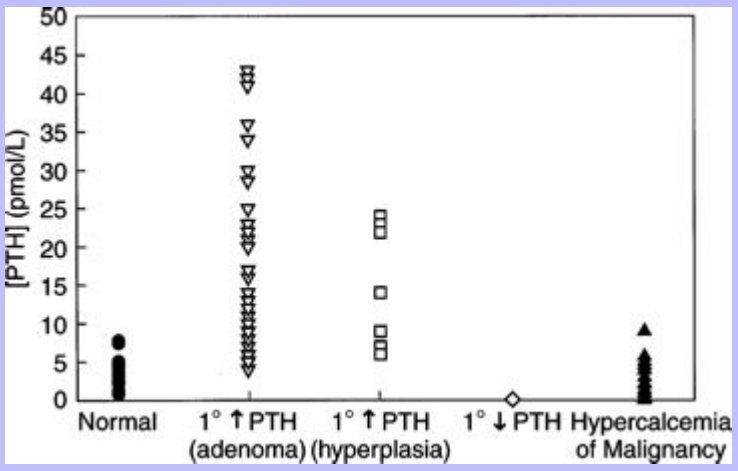
concentration. In healthy animals, as the serum calcium concentration increases, the serum PTH concentration decreases. Relative to their hypercalcemia (using total or, preferably, ionized calcium), virtually all dogs and cats with PHPTH have excessive PTH secretion. In other words, serum PTH concentrations within the reference range should be considered "excessive" in a dog or cat with hypercalcemia. Such results are consistent with autonomous secretion of hormone.

Figure 237-4 **A,** Cervical ultrasonogram from a dog with a functional parathyroid adenoma. The reader should note the right thyroid lobe, in which a well-marginated, hypoechoic mass *(arrows)* is visible at the cranial pole of the thyroid. **B,** Solitary parathyroid adenoma removed from a dog with primary hyperparathyroidism. (Ultrasound courtesy of Dr. Tom Nyland and Dr. Eric Wisner, Davis, Calif.)



The "sandwich" (two-site immunoradiometric [IRMA] assay system) for measuring PTH is considered the most reliable assay system currently available for dogs. At least one serum PTH concentration was obtained from each of 162 dogs with PHPTH (see Table 237-5). Most laboratories have similar PTH reference ranges (2 to 13 pmol/L). The mean serum PTH concentration in these untreated dogs (11.9 pmol/L) was within the reference range, and 107 of the 162 results (66%) were within that reference range. Sixty-three dogs (39%) had serum PTH concentrations of 3.7 to 7.9 pmol/L; 44 dogs (27%) had values of 8 to 13 pmol/L; 25 dogs (15%) had results of 13.1 to 20 pmol/L; and 30 dogs (19%) had results greater than 20 pmol/L. The availability of both PTH and PTHrP assay results has improved clinicians' ability to identify the specific problem causing hypercalcemia in many dogs. These assays are accessible for practitioners.

Figure 237-5 Serum PTH concentrations for normal dogs and those with various disorders of calcium homeostasis. The reader should note that some overlap exists in test results. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders Co, 2004.)



237.1.11 Radionuclide Scans

Radionuclide procedures have been used as an aid for detecting and localizing parathyroid adenomas in humans.[29] The most commonly used radionuclide imaging technique uses technetium-99m-sestamibi.[30,31] Two reports suggested that this procedure might be helpful in localizing parathyroid adenomas in dogs with PHPTH.[32,33] In a subsequent study, double-phase parathyroid scintigraphy was evaluated in a group of hypercalcemic dogs, and only one of 10 dogs with PHPTH had a scan that correlated with surgery. The poor sensitivity and specificity achieved with scintigraphy led the authors to conclude that use of this tool could not be recommended.[34]

237.1.12 Selective Venous Sampling

An attempt was made to localize autonomously functioning parathyroid masses using serum PTH assay results from each jugular vein. The hypothesis was that the vein draining the side of the autonomously functioning mass would have greater amounts of PTH. Blood samples were obtained from each jugular vein prior to surgery from dogs with PHPTH caused by a solitary functioning adenoma. Unfortunately, a gradient between samples was only identified in one of 11 dogs, and the conclusion was that selective venous sampling was not reliable.[26]

237.1.13 Diagnostic Approach to the Hypercalcemic Dog or Cat

237.1.13.1 General

The list of differential diagnoses for hypercalcemia is relatively short (see Table 237-1; Box 237-3), allowing a logical approach to identifying its cause. The most common cause in the dog and cat is *malignancy-associated hypercalcemia*. In an attempt to be practical, logical, and cost-effective, the diagnostic approach should first identify or rule out an underlying malignancy.[35] Only after testing has failed to identify a malignancy should PHPTH be considered.

237.1.13.2 Review the History and Physical Examination

237.1.13.2.1 First steps

The diagnostic approach to the hypercalcemic dog or cat should be relatively straightforward (see Figure 237-2, *A* and *B*). The first step should be to confirm the presence of hypercalcemia by resubmitting a *second* blood sample for calcium and phosphorus determination, although the second sample virtually always has the same result as the first. Whenever possible, veterinary practitioners would be well served to submit appropriate samples for serum ionized calcium concentration. Such results, if increased, confirm hypercalcemia. If the ionized calcium concentration in a dog with confirmed increases in serum total calcium, is within or below the reference range, chronic renal failure or laboratory error should be considered. Review of the signalment, thorough history, and physical examination often allows the clinician to identify the cause for hypercalcemia or at least develop a likely list of high-priority possibilities. Both the history and physical examination should be repeated after the serendipitous finding of hypercalcemia.

237.1.13.2.2 Signalment

Signalment (age, gender, breed) is emphasized, in part, because of the remarkable incidence of PHPTH in the Keeshond and in dogs that are 8 years of age or older. Renal failure can occur at any age, but certain breeds are predisposed to familial renal problems (Shih Tzu, Lhasa Apso, Doberman pinscher). Young dogs are more likely to suffer from renal failure, malignancy (lymphosarcoma), or hypoadrenocorticism (especially in the female), whereas apocrine gland carcinoma of the anal sac, and other malignancies occur in older dogs.

237.1.13.2.3 History

The owner should be questioned about the pet's diet, vitamin-mineral supplementation, and exposure to rat and mouse poisons or houseplants that contain vitamin D analogues. One can attempt to determine if the pet is in pain (lytic bone lesions). Answers to questions regarding the presence of polydipsia, polyuria, appetite, and activity may be important. Generally, the more ill the pet appears the less likely that it has PHPTH (and the more likely it has a malignancy, renal failure, vitamin D toxicosis, granulomatous disease, or hypoadrenocorticism).

237.1.13.2.4 Physical examination

After assessing hydration status and severity of illness, the physical examination should include careful palpation of peripheral lymph nodes (lymphoma) and the mammary glands (mammary cancer). A thorough rectal and perirectal examination is imperative in the identification of an apocrine gland carcinoma of the anal sac. A digital vaginal examination should also be performed (vaginal tumor). The clinician should gently palpate as much of the skeleton as possible, searching for an area of focal bone pain that could then be pursued with radiographs (multiple myeloma). The kidneys should be palpated in an attempt to identify irregularities.

237.1.13.3 Initial Data Base

237.1.13.3.1 Blood and urine

The initial data base should include a hemogram (complete blood count [CBC]), a serum biochemical profile, serum ionized calcium concentration, urinalysis, and thoracic radiographs. The abdomen should be evaluated with ultrasonography, radiography, or both. If the serum phosphorus concentration is normal or low, renal failure, vitamin D toxicosis, and hypoadrenocorticism are less likely (see Figure 237-2, *A* and *B*). The serum creatinine, sodium, potassium, and BUN concentrations are extremely valuable in this assessment as well. A sodium-to-potassium ratio less than 27:1 is consistent with, but not diagnostic of, adrenal insufficiency. An ACTH stimulation test should be performed if this disease is possible. Low, low-normal, or normal serum phosphate concentrations are consistent with PHPTH and malignancy-associated hypercalcemia. Striking increases in total protein concentrations, specifically due to a monoclonal spike, are classic for multiple myeloma.

237.1.13.3.2 Parathyroid versus primary renal disease

A diagnostic dilemma exists when hyperphosphatemia and hypercalcemia coexist with azotemia. The clinician must determine whether the hypercalcemia is the cause or the consequence of renal disease. Other abnormalities in the initial data base may support renal failure as the primary problem. These abnormalities include marked increases in serum phosphorus concentration, low-normal or low serum ionized calcium concentrations, nonregenerative anemia, proteinuria, and palpably or radiographically small and irregular kidneys. The serum ionized calcium in dogs with PHPTH is increased. If the hypercalcemia dissipates with aggressive fluid therapy and diuresis, PHPTH is less likely than primary renal failure or hypoadrenocorticism.

237.1.13.3.3 Radiography and ultrasonography

Radiography of the thorax and ultrasonography of the abdomen should be evaluated for soft tissue masses, soft tissue calcification, evidence of fungal disease, organomegaly, osteolysis, or osteoporosis. The goal is to identify an abnormal area that could be biopsied to provide a definitive explanation for hypercalcemia. An anterior mediastinal mass is demonstrable radiographically in as many as 40% of hypercalcemic dogs with lymphosarcoma.[36] If hepatomegaly or splenomegaly is identified, histology of a biopsy (obtained percutaneously) taken from either of these organs should be evaluated to help establish a diagnosis. Adenocarcinomas derived from the apocrine glands of the anal sac may appear radiographically as a mass in the pelvic canal. Sublumbar lymphadenopathy due to tumor metastasis is also common. Soft tissue calcification is most frequently observed with hypervitaminosis D or chronic renal failure, although mineralization can be seen with any hypercalcemic disorder in association with hyperphosphatemia and a calcium × phosphorus product greater than 60 to 80.

1518

1519

Discrete lytic lesions in the vertebrae or long bones are suggestive of either myeloma or malignancy-associated hypercalcemia with bone metastasis. Radionuclide bone scans can be performed at specialty centers to identify bone lesions not detected with radiographs. Concurrent hyperproteinemia is supportive of myeloma. Solid tumors with metastasis to bone are more likely if lytic bone lesions and normoproteinemia (especially normal serum globulin concentrations) are present. A core biopsy of a lytic lesion may be necessary to establish a definitive diagnosis.

Ultrasonography of the cervical region has been reviewed. This tool is noninvasive and easily used. Identification of a solitary mass within or near one thyroid lobe supports the diagnosis of PHPTH, if the dog is not in renal failure.[22] This tool requires the 10-MHz transducer and, most importantly, the results are subjective.

237.1.13.4 Lymph Node and Bone Marrow Evaluations

If the initial data base has not established a diagnosis, the next diagnostic steps should include evaluation of lymph nodes, bone marrow, or both. Because lymphosarcoma is the most common neoplasm associated with hypercalcemia in the dog and cat, peripheral nodes should be palpated. Ideally, the largest lymph node (*not* the submandibular node) should be assessed for histologic evaluation. Needle aspirates for cytology are occasionally acceptable, but pathologists may be hesitant to make a definitive diagnosis based on cytology alone. If any abnormalities are found on cytologic evaluation of an aspirate, histologic evaluation of a large biopsy sample or lymph node excision should be obtained to establish or rule out the diagnosis. This step should be omitted in dogs that are relatively healthy, based on an index of suspicion against the diagnosis of lymphosarcoma.

A bone marrow aspirate should also be considered in the hypercalcemic pet because the lymphosarcoma may be associated only with invasion of the marrow by neoplastic cells.[37] As with the peripheral lymph node evaluation, presence of a normal bone marrow aspirate does not definitively rule out lymphosarcoma. We usually omit a bone marrow aspirate when a dog is clinically well and when its CBC is unremarkable.

237.1.13.5 Serum PTH and PTHrP Concentrations

Assay for these hormone concentrations can be quite helpful. Because the evaluation of hypercalcemic dogs tends to be logical, each step has the potential for ruling out causes. The diagnosis of PHPTH can be reached by simple exclusion. In other words, as all other differential diagnoses are eliminated, PHPTH may remain as the only reasonable diagnosis. Treatment of most of the dogs in our series for PHPTH was completed before the results of serum PTH concentrations were available.

237.1.14 Acute Medical Therapy for the Hypercalcemic Dog

237.1.14.1 Primary Hyperparathyroidism versus (PHPTH) Other Disorders

237.1.14.1.1 PHPTH

The primary mode of therapy for severe hypercalcemia should be aimed at resolving its underlying cause. Surgical excision of abnormal parathyroid tissue is the most common therapy for dogs and cats with PHPTH. In these animals, however, hypercalcemia is neither an acute problem nor is the calcium × phosphate product greater than 60 to 80. Therefore conditions developing secondary to hypercalcemia (other than uroliths) are not usually a concern in dogs with PHPTH.

237.1.14.1.2 Renal failure or vitamin D toxicosis

Severity of clinical signs and degree of damage to nephrons appears dependent, in part, on serum phosphorus concentrations via the calcium × phosphate product. Renal damage (nephrotoxicity) induced by metastatic mineralization is thought to correlate with serum Ca × PO_4 product greater than 60 to 80.

Thus hypercalcemia associated with PHPTH is less worrisome and dangerous than the hypercalcemia associated with renal failure or hypervitaminosis D. The latter two disorders are almost always accompanied by hyperphosphatemia, a problem that amplifies the potential of soft tissue calcification (see Table 237-6).

237.1.14.2 Indications

237.1.14.2.1 Source of illness versus need for treatment

Clinically, both to owners and veterinarians dogs with PHPTH appear relatively healthy. Further, despite having dramatic increases in serum calcium concentration (mean serum calcium concentrations > 14 mg/dL; see Table 237-5), dogs and cats with PHPTH are usually not in need of acute therapy because, in part, their calcium × phosphate products are not worrisome (see Table 237-6). In contrast, dogs with concurrent lymphosarcoma and hypercalcemia often exhibit extremely worrisome clinical signs that are caused by their malignancy rather than the hypercalcemia. Treatment for cancer often indirectly decreases serum calcium concentrations. Dogs that have mild hypercalcemia and renal failure or vitamin D toxicosis also usually have worrisome clinical signs and moderate to severe hyperphosphatemia. They are at risk for tissue mineralization and they benefit from treatment directed specifically at decreasing the calcium × phosphorus product. Dogs with apocrine gland carcinoma of the anal sac or those with “other” malignancies (e.g., multiple myeloma) also tend to be much more ill than dogs with PHPTH.

237.1.14.2.2 Indications for symptomatic treatment

Because of the deleterious effects of hypercalcemia on renal, cardiovascular, or neurologic function, it may become necessary to treat a dog or cat symptomatically in an attempt to lower the blood calcium concentration while completing tests to establish a diagnosis. The decision to implement symptomatic therapy should be based on the severity of the pet's clinical signs, the rapidity of progression of these signs, and the status of renal, cardiac, and neurologic function. *No specific serum calcium concentration exists above which therapy must be initiated.*

Table • 237-6 Typical Serum Calcium and Phosphate Concentrations for Various Conditions

	TYPICAL SERUM CALCIUM (MG/DL)	TYPICAL SERUM PHOSPHATE (MG/DL)	TYPICAL CALCIUM × PHOSPHATE PRODUCT*
Normal dog	10	4.5	45
Primary hyperparathyroidism	14.3	2.8	40
Lymphosarcoma	15	3.0	45
Apocrine cell carcinoma of the anal sac	15	3.0	45
Chronic renal failure	11.5	10	115
Vitamin D toxicosis	11.5	10	115

* Aggressive therapy is recommended when the product of these two electrolytes exceeds 60 to 80. For most conditions causing hypercalcemia, emergency therapy is not necessary to reduce the serum calcium concentration.

Therapy for hypercalcemia is indicated when dehydration, azotemia, cardiac arrhythmia, severe neurologic dysfunction, or weakness exists.[6,38] Death or encephalopathy directly attributable to hypercalcemia (except after ingestion of large amounts of rat poison containing vitamin D) is extremely uncommon. Therapy (intravenous fluids ± furosemide) may be indicated in a relatively stable dog or cat in which progressive metastatic calcification of soft tissues is suspected. Tissue mineralization can be assumed when the calcium × phosphorus product exceeds 60 to 80. With a product below 60, no urgent need exists to lower the serum calcium concentration, because the risk for soft tissue mineralization is not great.[39] Several methods have been suggested to control acute or severe hypercalcemia (Box 237-4 and Table 237-7). In dogs and cats, saline diuresis, diuretic therapy with furosemide or ethacrynic acid, and corticosteroids are the most commonly used modes of therapy. As a general rule, diuretic therapy and saline diuresis can be initiated without interfering with the diagnostic evaluation. Because the incidence of hypercalcemia associated with lymphosarcoma is great, glucocorticoids should not be administered unless a specific diagnosis has been confirmed.

237.1.14.3 Fluid Therapy

237.1.14.3.1 Correction of fluid deficits

The primary indication for fluid therapy is dehydration. Decreases in fluid intake due to nausea and vomiting, plus an inability to concentrate urine, are common causes for dehydration in hypercalcemic dogs and cats. Dehydration, in turn, impairs calcium excretion by reducing GFR and increasing renal tubular absorption of calcium.[40] Dehydration also causes hemoconcentration, hyperproteinemia, and further increases in total and ionized serum calcium concentrations. Correction of fluid deficits should reduce the severity of hypercalcemia, although it usually does not return serum calcium concentrations to normal except in dogs with hypoadrenocorticism or those that are not, in fact, hypercalcemic. In humans, a rapid fall of 2 to 3 mg/dL in total serum calcium concentration is typical after rehydration.[3]

Box • 237-4 General Treatment of Hypercalcemia

237.1.14.3.1.1.1

Definitive

Remove underlying cause

237.1.14.3.1.1.2

Supportive

Initial considerations

- Fluids (0.9% sodium chloride)
- Furosemide
- Sodium bicarbonate
- Glucocorticosteroids

Secondary considerations

- Bisphosphonates
- Calcitonin

Tertiary considerations

- Mithramycin
- Ethylenediamine tetra-acetic acid (EDTA)
- Peritoneal dialysis, homodialysis

Future considerations

- Calcium channel blockers
- Somatostatin congeners
- Calcium receptor agonists

Nonhypercalcemic calcitriol analogues

237.1.14.3.2 Saline diuresis

Once fluid deficits have been corrected, saline diuresis should promote continuing renal loss of calcium; an effective short-term therapy for any cause of hypercalcemia. Physiologic saline promotes calciuresis because the large amount of filtered sodium competes with calcium for renal tubular resorption.[40] Increased sodium excretion leads to increased calcium excretion. Normal saline given at two to three times the maintenance rate (120 to 180 mL/kg/day) is usually effective. Potassium supplementation is often necessary to prevent hypokalemia. The pet should also be monitored carefully to detect adverse effects (e.g., pulmonary edema) resulting from administration of large fluid volumes. Monitoring body weight, urine output, blood pressure, central venous pressure (CVP), and auscultation of the thorax are recommended.

237.1.14.4 Diuretic Therapy

The use of potent diuretics, in conjunction with saline diuresis, ensures maximal urinary sodium excretion and, in turn, calciuresis. Volume expansion must precede administration of furosemide. Furosemide enhances the calciuric effects of volume expansion by inhibiting calcium reabsorption in the thick ascending limb of the loop of Henle. Furosemide should also prevent severe volume overload.[6] Recommended protocols typically suggest a 5 mg/kg intravenous bolus followed by 2 to 4 mg/kg given twice a day or three times a day.[41] Thiazide diuretics should not be used because they decrease renal calcium excretion and may exacerbate hypercalcemia by enhancing distal tubular reabsorption.[6]

237.1.14.5 Glucocorticoids

The beneficial effects of glucocorticoids in the symptomatic management of hypercalcemia include reducing bone resorption of calcium, decreasing intestinal calcium absorption, and increasing renal calcium excretion. Glucocorticoids are cytotoxic to neoplastic lymphocytes and inhibit growth of neoplastic tissue, accounting for their beneficial effects in lymphoma and multiple myeloma. They counteract effects of vitamin D toxicosis or granulomatous diseases. In general, nonhematologic cancers do not respond to glucocorticoids nor do animals with PHPTH.[42] Administration of glucocorticoids should be delayed until a definitive diagnosis has been established. Lymphosarcoma is the most common cause of hypercalcemia in the dog, but the administration of glucocorticoids may interfere with subsequent ability to confirm this diagnosis. Prednisone or prednisolone (1 to 2 mg/kg twice a day) or dexamethasone (0.1 to 0.2 mg/kg twice a day) can be used in the management of hypercalcemia. These drugs can be given orally, subcutaneously, or intravenously.

237.1.14.6 Bisphosphonates

The bisphosphonates are compounds structurally related to pyrophosphate, a normal metabolic by-product. The chief property of these compounds is their inhibitory effect on osteoclast function and viability.[43] GI absorption is poor (< 10%), but intravenous administration has been effective in treating hypercalcemic humans.[6] Considering the early occurrence of bone resorption and bone loss in humans with multiple

myeloma, for example, the benefit of bisphosphonates are impressive, even in humans who have no osteolytic lesions at the start of therapy. These drugs have beneficial skeletal effects and also slow tumor growth by inhibiting the production by osteoblasts of interleukin-6 (IL-6), a growth factor essential to myeloma cells.[44] Three bisphosphonates (etidronate, clodronate, and pamidronate) are approved in western countries for treatment of hypercalcemia in humans. Availability of other potent bisphosphonates (aminohexane bisphosphonate, risedronate, and alendronate) and other inhibitors of bone resorption (gallium nitrate, paclitaxel) open new avenues for more efficient treatment of hypercalcemia and bone disease. Clodronate was used successfully for treatment of lymphoma-induced hypercalcemia in one dog and vitamin D toxicosis in one dog.[45] Pamidronate has been used successfully to reverse vitamin D–induced toxicosis in dogs.[46,47]

Table • 237-7 Specific Treatment of Hypercalcemia (Not Needed in Primary Hyperparathyroidism)

TREATMENT	DOSE	INDICATIONS	COMMENTS
Volume Expansion			
SQ saline (0.9%)*	75–100 mL/kg/day	Mild hypercalcemia	Contraindicated if peripheral edema is present.
IV saline (0.9%)*	100–125 mL/kg/day	Moderate to severe hypercalcemia	Contraindicated in congestive heart failure and hypertension.
Diuretics			
Furosemide	2–4 mg/kg bid to tid IV, SQ, P0	Moderate to severe hypercalcemia	Volume expansion is necessary before use of this drug.
Alkalinizing Agent			
Sodium bicarbonate	1 mEq/kg IV slow bolus; may continue at 0.3 × base deficit × wt in kg/day	Severe hypercalcemia	Requires close monitoring.
Glucocorticoids			
Prednisone	1–2.2 mg/kg bid P0, SQ, IV	Moderate to severe hypercalcemia	Use of these drugs before identification of cause may make definitive diagnosis difficult!
Dexamethasone	0.1–0.22 mg/kg bid, IV, SQ		
Bone Resorption Inhibitors			
Calcitonin	4–6 IU/kg SQ bid to tid	Hypervitaminosis D	Response may be short-lived. Vomiting may occur.
Bisphosphonates			
EHDP-Didronel	15 mg/kg q24h to bid	Moderate to severe hypercalcemia	All are expensive, and use in dogs is limited.
Clodronate	20–25 mg/kg in a 4-hr IV infusion		Clodronate is approved for use in humans in Europe; availability in United States may be limited.
Pamidronate	1.3 mg/kg in 150 mL 0.9% saline in a 2-hr IV infusion, can repeat in 1 week		
Mithramycin	25 µg/kg IV in 5% dextrose over 2–4 hr q2-4 wk	Severe hypercalcemia, refractory HHM	Limited use in dogs and cats. Nephrotoxicity, hepatoxicity, thrombocytopenia.
Miscellaneous			
Sodium EDTA	25–75 mg/kg/hr	Severe hypercalcemia	Nephrotoxicity.
Peritoneal dialysis	Low calcium dialysate	Severe hypercalcemia	Short duration of response. Use in hypercalcemia not reported.

HHM, Humoral hypercalcemia of malignancy.

* Potassium supplementation is necessary. Clinician should add 5 to 40 mEq KCl/L depending on serum potassium concentration.

237.1.14.7 Calcitonin

Calcitonin reduces osteoclast activity and the formation of new osteoclasts. It may be effective, at least temporarily, in decreasing serum calcium concentrations in those cases of hypercalcemia associated with

excessive osteoclastic activity.[40] In humans, calcitonin has not been uniformly effective in lowering serum calcium concentration, either because the mechanisms of hypercalcemia induced by the disease are nonresponsive to calcitonin or because patients become refractory to its effects. The drug has been described as "weak," short-acting, and having few side effects.[6,48,49]

Salmon calcitonin (Calcimar solution, USV Laboratories, Tarrytown, New York) is the most potent congener available. Reports in the veterinary literature support use of this drug for the treatment of cholecalciferol rodenticide intoxication. Several doses have been reported, but the number of dogs and cats in which the drug has been used is too small for recommendations regarding their effectiveness. Some reported doses in dogs include 4.5 U/kg subcutaneously every 8 hours; 8 U/kg subcutaneously every 24 hours; and 5 U/kg subcutaneously every 12 hours.[50,51] In cats, 4 U/kg intramuscularly every 12 hours was used successfully.[52]

1521
1522

237.1.14.8 Plicamycin (Mithramycin)

Plicamycin (previously termed *mithramycin*) is a cytotoxic compound initially evaluated as a cancer chemotherapeutic agent. This agent is a potent inhibitor of RNA synthesis in osteoclasts and an effective treatment for hypercalcemia. Significant toxicity, including thrombocytopenia, hepatic necrosis, renal damage, and hypocalcemia has been caused by the drug. Clinically significant toxicity was not observed in normal dogs after two IV treatments. Shivering was noted during the infusion, and osteoclastic activity was reduced.[53,54] Two doses have been reported: 25 g/kg and 50 g/kg once or twice weekly, to control hypercalcemia.[55] Effects of this drug on serum total and ionized calcium concentrations were studied in nine dogs with hypercalcemia of malignancy, one dog with PHPTH, and one dog with vitamin D toxicosis. High-dose mithramycin (100 g/kg) caused fatal acute hepatocellular necrosis in two dogs. Low doses (25 g/kg) were effective in normalizing total and ionized calcium concentrations within 24 to 48 hours in six of nine dogs, including a dog with vitamin D toxicosis. The effects were short lived (1 to 3 days) in three dogs and lasted longer (about 7 days) in three dogs. Side effects were mild in dogs treated with the low dose and included mild GI signs in three dogs and reduction in platelet counts in three dogs. The low dose did not cause evidence of hepatic disease, reduce tumor size, or reduce PTHrP concentrations.[54]

237.1.14.9 EDTA

The intravenous injection of sodium EDTA has been used to reduce ionized calcium concentrations immediately in humans with life-threatening hypercalcemia. Infused EDTA forms complexes with ionized calcium that are rapidly excreted by the kidney.[40] A dose of 25 to 75 mg/kg/hr has been suggested as a starting point for the treatment of hypercalcemia in the dog.[21] Unfortunately, EDTA is nephrotoxic, and acute renal failure may be a consequence of its infusion.

237.1.14.10 Bicarbonate

The ionized fraction of serum calcium is determined partly by an animal's acid-base status. Correcting acidosis or creating a slight alkalosis with bicarbonate therapy shifts ionized calcium to the protein-bound fraction, rendering it less harmful.[39] A dose of 1 to 4 mEq/kg has been recommended.[56] A single intravenous dose may last as long as 3 hours in normal cats.[57] The effect of the drug is mild, and it may be helpful when administered with other treatments.

237.1.14.1 Dialysis

Hemodialysis and peritoneal dialysis with calcium-free dialysate solutions have been used effectively in humans to lower serum calcium concentrations when other methods have failed.[3,40] These techniques are particularly effective in patients with severe renal failure because fluid and diuretic therapy depends on enhanced renal excretion of calcium. Significant quantities of phosphate may also be dialyzed from the blood. Because phosphate depletion may aggravate hypercalcemia, serum phosphorous concentrations should be monitored and supplements given as required.

237.1.14.2 Calcium Receptor Agonist Therapy

Medical therapy for PHPTH has been limited, although new approaches have followed discovery of a calcium-sensing receptor on parathyroid cells that down-regulate synthesis and secretion of PTH. Molecules that mimic the effect of extracellular calcium could also activate this receptor and inhibit parathyroid cell function. The Phenylalkylamine (R)-N-(3-methoxy-alpha-phenylethyl)-3-(2-chlorophenyl) -1-propylamine, or R-5658, is one such calcimemetic compound. The drug did reduce serum PTH and ionized calcium concentrations in postmenopausal women with primary hyperparathyroidism.[58]

237.1.15 Surgical Therapy for Primary Hyperparathyroidism

237.1.15.1 Assessing the Parathyroid Glands During Surgery

237.1.15.1.1 How many glands are involved?

Surgical techniques for removing parathyroid tumors are described in various textbooks. It is important to attempt identification and evaluation of all four parathyroid glands before deciding on which gland or glands to remove. However, most dogs with PHPTH only have one obvious gland because the others are atrophied. About 90% of dogs with PHPTH have a solitary, autonomously functioning, parathyroid mass. Virtually all of the remaining dogs have two abnormal glands. Once an ultrasonographer demonstrates competence at identifying parathyroid glands and parathyroid tumors, the clinician should be reluctant to send any dog suspected of having PHPTH to surgery if an abnormal parathyroid mass or masses are not seen via cervical ultrasonography. Visualizing a mass supports the diagnosis and informs the surgeon where abnormal tissue is located. The process of evaluating parathyroid tissue at surgery without prior ultrasound evaluation can be extremely easy or quite difficult. The surgeon may easily visualize enlargement of one (common), two (less common), or more than two glands (rare). However, abnormal parathyroid tissue may not be readily identified. Any enlarged or abnormal tissue should be removed and submitted for histologic evaluation, assuming that three or fewer parathyroids appear enlarged, discolored, or both. The remaining intact gland or glands should prevent permanent hypoparathyroidism, although transient hypocalcemia may develop after surgery due to atrophy of normal glands after chronic suppression by the autonomously functioning abnormal gland or glands. An attempt must be made to ensure that at least one parathyroid gland remains intact to maintain calcium homeostasis and prevent permanent hypocalcemia. If none of the parathyroid glands appear enlarged or if all appear small, the diagnosis of primary PHPTH must be questioned. Uniform enlargement of all four glands should make one suspicious of a secondary condition.

Intravenous methylene blue infusion (3 mg/kg) has been described as a tool for improving a surgeon's ability to recognize abnormal glands. Three dogs with PHPTH were evaluated, and each had a tumor identified after new methylene blue infusion. Two of the three dogs developed anemia, Heinz bodies, and red blood cell (RBC) "blistering" after the procedure.[59] This procedure is not recommended.

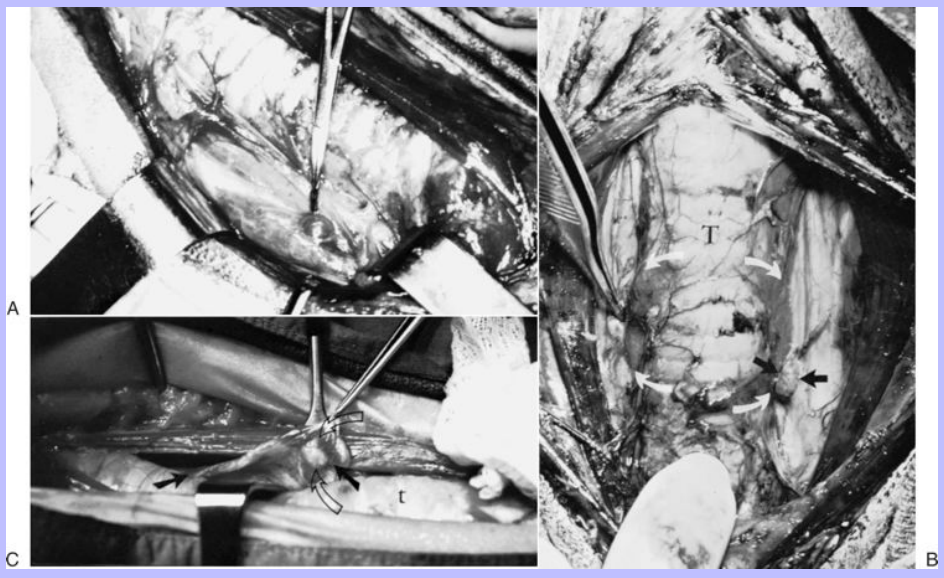
237.1.15.1.2 The solitary adenoma, hyperplastic nodule, or carcinoma

Almost all dogs with PHPTH have a solitary, easily identified, parathyroid adenoma. Fourteen of the 187 dogs with PHPTH in our series had parathyroid masses that at surgery appeared to be typical adenomas but histologically were diagnosed as carcinoma. Another 12 dogs had parathyroid masses that were classified as hyperplasia.[60] Approximately one half of tumors have been identified on the ventral surface of the thyroid glands. If not seen on the ventral surface, careful inspection of the dorsal surface of each thyroid lobe usually reveals the mass as a discrete structure on, or within, the adjacent thyroid tissue (Figure 237-6). "External" parathyroid adenomas have been easily removed without damage to surrounding tissue. Surgeons may choose to remove the entire thyroid-parathyroid structure in dogs with an "internal" parathyroid adenoma. In about 5% of dogs, the surgeon was not able to identify abnormal tissue and removed the thyroid lobe suggested by cervical ultrasonography as containing the parathyroid mass. In each case, that decision was correct.

237.1.15.1.3 Enlargement of multiple parathyroid glands

When more than one enlarged gland is identified, the concern is primary versus secondary (renal or nutritional) hyperparathyroidism. The presurgical evaluation, as reviewed, should identify or eliminate secondary disease. If the clinician is convinced that primary disease is present, a decision to remove two glands is straightforward. However, if four glands are involved (an extremely rare situation), the decision should be based on clinical status, renal function, and ability of the owner to treat permanent hypoparathyroidism.

Figure 237-6 **A,** Surgical site during removal of a solitary parathyroid adenoma *(tip of forceps)*. **B,** Surgical site during removal of a solitary parathyroid adenoma. White arrows delineate the cranial and caudal poles of the thyroid glands; black arrows point out the parathyroid adenoma. **C,** Surgical site during removal of an "internal" parathyroid adenoma. Solid arrows delineate the cranial and caudal poles of the thyroid, which is being retracted from the trachea to reveal the parathyroid adenoma *(open arrows)* on the dorsal surface of the thyroid. *T,* trachea. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders Co, 2004.)



Only 14 of 187 dogs with PHPTH (7%) had enlargement of more than one gland each. Of these 14 dogs, each of 13 dogs had two enlarged glands and one had four enlarged glands. Each of three dogs had two "hyperplastic" parathyroids, each of three dogs had two parathyroid adenomas, each of three dogs had one adenoma and one hyperplastic gland, each of two dogs had one hyperplastic gland and one carcinoma, and one of the dogs with two masses had one adenoma and one carcinoma (histologic classification is discussed in a following section). One of the 187 PHPTH dogs had enlargement of all four glands.[60] Each of these four glands were classified histologically as being hyperplastic. Enlargement of all four glands suggests either multiple adenomas or, more likely, parathyroid hyperplasia.

237.1.15.1.4 Recurrence of PHPTH

Sixteen of 187 dogs with PHPTH in our series had a solitary parathyroid mass removed surgically with resolution and then recurrence of their disease. In each case, resolution of the PHPTH persisted for at least 6 months, and in 13 of the 16 dogs, PHPTH had resolved for 12 to 30 months, whereas in three it lasted 6 to 12 months. Each dog then had recurrence of hypercalcemia caused by a second solitary, autonomously functioning, surgically removed parathyroid mass. The initial diagnosis in 11 dogs was parathyroid adenoma, three had a parathyroid carcinoma, and two had parathyroid hyperplasia. The histology report after the second surgery was the same in 12 dogs. However, two of the three dogs that initially had a parathyroid carcinoma had an adenoma at recurrence and one dog with an adenoma initially had a carcinoma removed at the second surgery. One dog with hyperplasia initially had an adenoma removed at the second surgery. Thus it is possible for the disorder to recur, suggesting that periodic rechecks of the serum calcium concentration after stabilization would be warranted. Seven of the 16 dogs were Keeshonden, and this breed may warrant more routine evaluations after initial treatment.

237.1.15.1.5 No parathyroid mass at surgery

If an enlarged parathyroid gland is not identified after thorough inspection of both thyroid areas by an experienced surgeon, careful exploration of the ventral neck should be completed and any abnormal tissue excised. The most likely explanation for not finding a parathyroid mass includes hypercalcemia due to occult neoplasia, PTH production by a parathyroid tumor located outside of the typical cervical region (in the cranial mediastinum), or the presence of a nonparathyroid tumor producing PTH (i.e., ectopic hyperparathyroidism). Presurgical cervical ultrasonography should identify a parathyroid mass. Failure to visualize a parathyroid mass would best be managed by obtaining another ultrasound opinion or delaying surgery for 1 to 3 months and then rechecking the cervical ultrasonography.

1523

1524

We have no experience with surgical exploration of the cranial mediastinum for a parathyroid mass. Such surgeries have inherent technical difficulties. The likelihood of finding ectopic abnormal parathyroid tissue is small. The greater likelihood of malignancy-associated hypercalcemia suggests that the decision to continue surgical exploration be carefully considered. Further diagnostic tests should be undertaken to identify occult neoplasia.

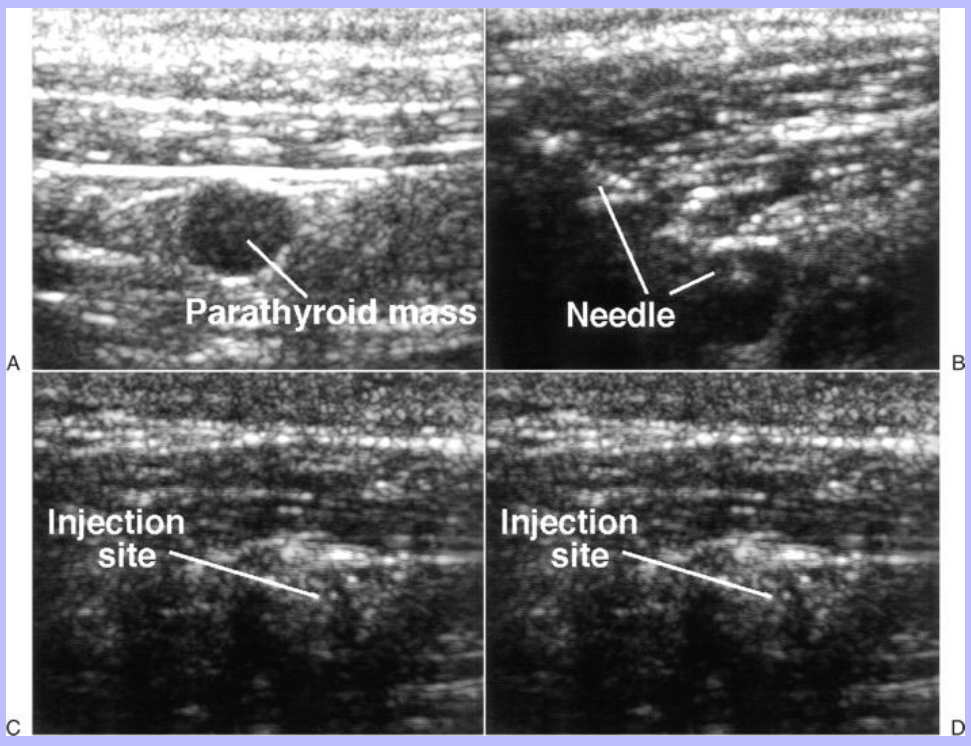
237.1.16 Novel Therapies for Primary Hyperparathyroidism in Dogs

237.1.16.1 Percutaneous Ultrasound-Guided Ethanol Ablation

Ultrasonography is an excellent method of identifying parathyroid masses in dogs with hypercalcemia secondary to PHPTH. Based on our experience with this tool as a diagnostic aid and studies performed on people with PHPTH,[61] we elected to assess the efficacy of ethanol ablation as a treatment for this disorder.[62] Ethanol causes coagulation necrosis and vascular thrombosis in the parenchyma of exposed tissue. PHPTH was diagnosed in 12 dogs. Their clinical and biochemical evaluation was typical for the disease. Each dog had a solitary hypoechoic round to oval mass near the thyroid gland on cervical ultrasonography. Parathyroid masses were identified on the right side of the neck in eight dogs and on the left in the other four. All the masses were 4 to 10 mm in length, located at the cranial aspect of one thyroid lobe in six dogs, within the caudal pole of a thyroid lobe in three dogs, and in the midbody of the thyroid

gland in three dogs. Calculated volume of the parathyroid masses ranged from 0.06 to 0.16 cm^3. It was assumed that each dog had a mass autonomously secreting PTH.

Figure 237-7 Ultrasonographic appearance of chemical ablation of a parathyroid mass in a dog. **A,** Sagittal view of the parathyroid mass prior to treatment. **B,** A 27-gauge needle is inserted into the mass. **C,** A test injection of 96% ethanol is used to confirm placement of the needle inside the mass. The reader should note that the ethanol is hyperechoic in relation to the parenchyma of the mass. **D,** After injection of the target dose of ethanol, the entire mass has an echogenic appearance. (From Long CD et al: Percutaneous ultrasound-guided chemical parathyroid ablation for treatment of primary hyperparathyroidism in dogs. J Am Vet Med Assoc 215:217, 1999, with permission.)



Each dog was placed under general anesthesia, and the ventral cervical region was clipped and aseptically prepared. The parathyroid mass was identified with ultrasound, and the tip of a 27-gauge needle, with tubing and syringe attached, was guided into the parathyroid using ultrasound (Figure 237-7). The approximate volume of the mass was matched with an equal volume of ethanol placed in the syringe. Ethanol was slowly injected into the mass with continuous ultrasound monitoring. The goal of therapy was

to inject enough ethanol to allow complete diffusion throughout the mass. The injection procedure requires a high-resolution transducer (10 MHz frequency) to allow assessment of the superficial tissues of the neck. Because parathyroid masses are small and sometimes in close proximity to nerves and vessels, considerable experience with ultrasound-guided needle placement is necessary.

Ethanol was easily seen with ultrasound during injection because it is hyperechoic (see Figure 237-7). Each parathyroid mass was injected with 50% to 150% of the calculated parathyroid volume. No dog was under anesthesia for more than 1 hour, and the mean duration of anesthesia was 38 minutes. A single injection was administered to 11 of the 12 dogs. One dog was injected a second time 48 hours after the first dose failed to decrease the serum calcium concentration into the reference range. All 12 dogs had decreases in serum total calcium concentration into the reference range. In 11 dogs this decrease was documented within 48 hours of injection (10 after the first injection and one after the second injection). One dog did not have resolution of its hypercalcemia until the fifth day post-treatment. One dog had a recurrence of hypercalcemia 30 days after injection and was treated surgically. Each of the other 11 dogs remained normal for more than 18 months. The only adverse side effect was a transient change in the "bark" in two dogs, potentially as a result of transient, unilateral, laryngeal paralysis injection of bilateral masses is not recommended. 1524 1525

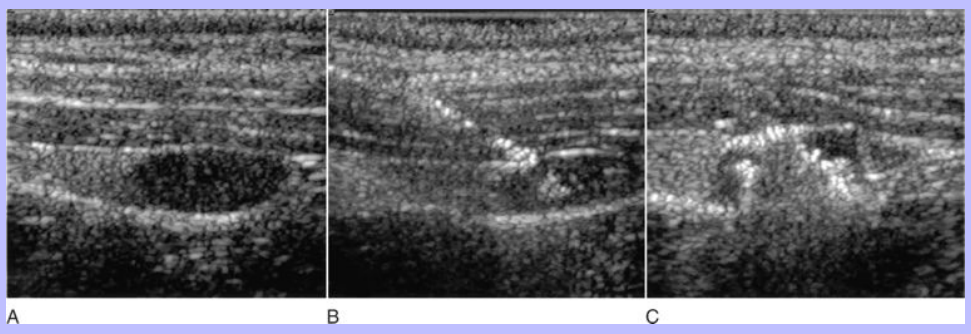
The conclusion of this study was that ultrasound-guided ethanol ablation was an efficacious mode of therapy for PHPTH in dogs. The cost of the procedure was considerably less than for surgery. Chemical ablation of parathyroid masses may be more effective in dogs than in humans because canine parathyroid masses are considerably smaller, thus requiring a smaller dose of ethanol for complete ablation.

237.1.16.2 Percutaneous Ultrasound-Guided Radiofrequency Heat Ablation

Heat destroys tissue by causing thermal necrosis. This form of therapy has several advantages as compared with ethanol ablation. First, radiofrequency damages a discrete quantity of tissue surrounding the noninsulated portion of the needle (no potential for "leakage" exists as with ethanol). Radiofrequency offers the additional advantage of not causing damage to regional vasculature. Vascular blood flow disperses heat from vessel walls. In humans, this treatment modality has a higher success rate than ethanol for ablation of masses, and fewer treatments are required to achieve remission. Radiofrequency heat ablation has been used in the treatment of multifocal hepatic masses and breast and nasal masses.[63,64] The disadvantage of radiofrequency is equipment cost.

Candidates for this procedure must have a parathyroid mass visible with ultrasonography; that mass must be large enough to have a needle inserted into it with ultrasound guidance (usually greater than 3 mm in diameter); the mass can not be subjectively considered too close to the carotid artery; and the dog should not have cystic calculi to be surgically removed because cervical surgery is a straight-forward addition to abdominal surgery. Since starting to use this treatment, 19 dogs did not meet the criteria for inclusion. An attempt was made to treat two dogs early in the study period, but the capsule could not be penetrated with the needle, and treatment was not attempted. Since then, a different more penetrating needle has been used. In one dog the parathyroid mass was too small for needle placement, and in four dogs the parathyroid mass was considered too close to the carotid artery for safe needle placement. Twelve dogs had cystic calculi that required surgical removal. In each of these dogs, parathyroid surgery and abdominal surgery were performed at the same time.

Figure 237-8 Left lateral sonographic images of an oval hypoechoic parathyroid nodule in a dog prior to heat ablation **(A)**, with the insulated needle passing through the superficial soft tissues into the cranial aspect of the mass **(B)**, and after heat ablation **(C)**. The reader should note the hyperechoic foci in the parenchyma of the gland in **C**. (From Pollard RE et al: Percutaneous ultrasonographically guided radiofrequency heat ablation for treatment of primary hyperparathyroidism in dogs. J Am Vet Med Assoc 218:1106, 2001, used with permission.)



Between September of 1999 and January of 2003, 33 dogs with PHPTH were treated with percutaneous heat ablation. Each dog had clinical and biochemical features that were typical for PHPTH. A solitary parathyroid nodule was identified by use of cervical ultrasonography in 26 dogs, seven dogs had two nodules each (a total of 40 masses in the 33 dogs). Five of these seven dogs had both nodules on the left side of the neck and two dogs had one nodule associated with each thyroid lobe. The ultrasonic appearance of the 40 masses was similar. All masses were spherical or ovoid and hypoechoic to the surrounding thyroid parenchyma. Length varied from 3 to 20 mm. Each dog with a solitary parathyroid mass was treated once. Each dog with two parathyroid nodules on the same side of the neck had both masses treated during the initial anesthesia. Each nodule was treated separately, 30 days apart, in the two dogs with one nodule on each side of the neck.

Each dog was placed under general anesthesia and the ventral cervical region was clipped and aseptically prepared. The parathyroid mass was identified with ultrasound, and the tip of a 20-gauge, over-the-needle (insulated) catheter, was directed into the mass using ultrasound guidance. An insulated wire connected the needle with the radiofrequency unit (Radiotherapeutics, Inc., Redwood City, California). Initially, 10 watts of energy was applied to the tissue for 10 to 20 seconds. If echogenic bubbles were not sonographically viewed at the needle tip during this time, the wattage was increased. Two-watt incremental increases were continued every 5 to 10 seconds until echogenic foci became apparent (Figure 237-8). Further, if an audible popping sound could be heard, the maximum heat application was arbitrarily determined to have been reached and additional wattage increases were not made. The needle was arbitrarily redirected multiple times, if necessary, in an attempt to completely ablate each mass. Mean anesthesia time was about 40 minutes, but this progressively decreased as experience with this procedure increased.[65]

The procedure was uniformly successful in these 33 dogs as demonstrated by the dramatic reduction in serum PTH and normalization of both total and ionized calcium concentrations that occurred within days of heat ablation. Serum calcium concentrations have remained within the reference range for more than 1 year. One dog improved for only 1 month and was treated surgically after hypercalcemia recurred. One dog with a unilateral parathyroid mass developed a transient voice change immediately after heat ablation, which resolved within 5 days. It is uncertain whether this voice change was secondary to intubation or the ablation procedure. Signs of pain, swelling, or respiratory distress were not detected in any of the dogs. Fifteen of the dogs required vitamin D therapy for postablation hypocalcemia (see following section). This is currently our preferred mode of treatment for dogs with PHPTH that do not have cystic calculi.

237.1.17 Post-Treatment Management of Potential Hypocalcemia

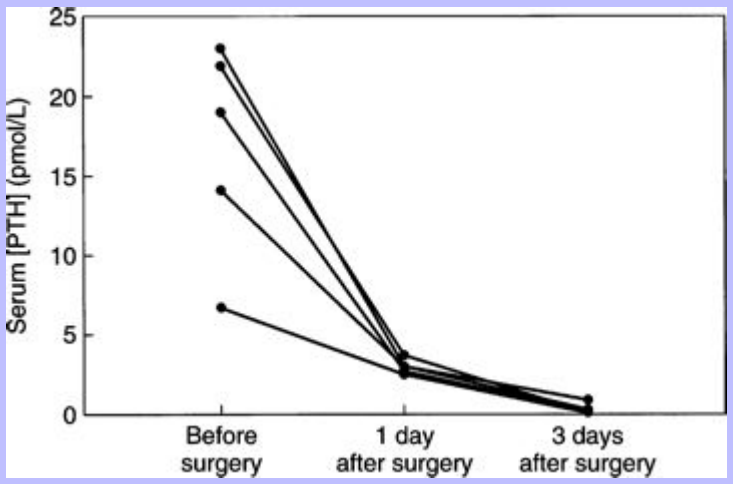
237.1.17.1 Background

Normal parathyroid glands atrophy if their function has been suppressed for a prolonged time due to autonomous secretion of PTH by a parathyroid adenoma, carcinoma, or primary hyperplasia. Surgical removal or ablation of this source for PTH results in a rapid decline in circulating PTH concentration (Figure 237-9) and a corresponding decline in serum calcium concentrations. This process typically takes place over a period of 1 to 7 days. Risk of post-treatment hypocalcemia correlates with the duration and severity of hypercalcemia prior to surgery (i.e., the higher the pretreatment calcium and the longer a dog has been hypercalcemic, the greater the risk of hypocalcemia after resolution of the PHPTH). Beginning vitamin D therapy immediately prior to or after surgery does not prevent decreases in serum calcium concentrations to or below the reference range but usually helps to avoid worrisome hypocalcemia or tetany.

237.1.17.2 Presurgical Serum Calcium Concentration Less than 14 mg/dL

If the serum calcium concentration prior to surgery is less than 14 mg/dL, the risk of postsurgical hypocalcemia is relatively small. Results between 14 and 15 mg/dL are inconsistent. The recommendation is to hospitalize such dogs for at least 5 days after surgery to monitor total serum calcium concentrations once or twice daily. Hospitalization also reduces a dog's activity by maintaining it in a cage or run. Active hypocalcemic dogs are at greater risk for clinical tetany than those kept quiet. If the total serum calcium concentration remains above 8.5 mg/dL (assuming a lower reference limit of 9 to 10 mg/dL), treatment for hypocalcemia is not recommended. If the serum ionized calcium concentration remains above 0.8 mmol/L (assuming a lower reference limit of about 1.1 mmol/L), treatment is not recommended. The reader should note, however, that these are general recommendations. It would never be incorrect to begin vitamin D therapy if one is concerned about rate of decrease in calcium or simply one wishes to be proactive. If the serum calcium concentrations decline below the limits suggested, or if clinical signs of hypocalcemia are observed (Box 237-5), treatment with vitamin D (± calcium) is suggested.

Figure 237-9 Serum PTH concentrations before and after surgery in eight dogs in which a solitary functional parathyroid adenoma was removed. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders Co, 2004.)



237.1.17.3 Presurgical Serum Calcium Concentration Greater than 15 mg/dL

The higher the presurgical serum calcium concentration, the more chronic the hypercalcemic condition, or both, the more likely it is that a dog will become clinically hypocalcemic after resolution of PHPTH. Knowing the duration of hypercalcemia would be valuable but is often not possible in dogs or cats. It can be assumed that dogs with serum calcium concentrations persistently greater than 15 mg/dL due to PHPTH have been hypercalcemic for sometime. It is recommended to prophylactically attempt to avoid hypocalcemia after surgery in this population of dogs by beginning vitamin D (Hytakerol or Calcitriol) ± calcium therapy the evening before or the morning of surgery or immediately after recovery from anesthesia. In some cases we have begun vitamin D therapy 24 to 36 hours *before* surgery because of the known delay in onset of vitamin D action. This becomes important in dogs severely hypercalcemic prior to surgery (>18 mg/dL). Initiation of these treatments has not prevented decreases in serum calcium concentration to or below reference ranges after surgery. Each dog should be kept quiet in the hospital for at least 5 days after treatment. Postsurgical hypocalcemia has been documented as quickly as 12 hours after surgery to as long as 20 days later. Most become hypocalcemic between 2 and 6 days after surgery. Tetany, when it has occurred, is most commonly seen 4 to 7 days after treatment. The serum calcium concentration should be monitored once or twice daily.

The goal of calcium and vitamin D therapy is to maintain the serum calcium concentration slightly low to low-normal (i.e., 8 to 9.5 mg/dL). These serum calcium levels prevent clinical signs of hypocalcemia and minimize risk of hypercalcemia while simultaneously being low enough to stimulate recovery of function in atrophied parathyroid glands. In addition, one should avoid mid-to high-normal or increased serum calcium

concentrations. Such levels of calcium are typically associated with increases in serum phosphate concentrations and predispose the dog to tissue mineralization.

237.1.17.3.1

Box • 237-5 Clinical Signs Associated with the Acute Onset of Hypocalcemia

Panting

Nervousness

Muscle trembling, twitching

Leg cramping, pain

Ataxia, stiff gait

Facial rubbing

Focal or generalized seizures

Biting of the feet

As the parathyroid glands regain control of calcium homeostasis, calcium and vitamin D supplements can be gradually withdrawn. This process of returning parathyroid function in remaining glands is predictable, allowing the gradual withdrawal (tapering) of calcium and vitamin D supplements. Once the serum calcium concentration is stabilized and the dog has been returned to the owner, withdrawal of the supplements may be initiated. Vitamin D is usually withdrawn first by gradually extending the time between administration (e.g., twice daily to once daily for 2 weeks; to once every other day for 2 weeks; then once every third day for 2 weeks; then once every fourth day for 2 weeks; and finally once weekly for 2 to 4 weeks). The serum calcium concentration should be checked prior to each downward adjustment in dosing interval to prevent development of occult hypocalcemia. If the serum calcium concentration drops below 8 mg/dL, decreases in vitamin D supplementation should be delayed or the dose increased. The serum calcium concentration should remain above 8 mg/dL to minimize the risk of tetany. Once the vitamin D supplementation has been reduced to once weekly for a period of 2 to 4 weeks, it may be discontinued. If the serum calcium concentration remains within the normal range, the calcium supplements can then be gradually withdrawn. The entire withdrawal process for vitamin D and calcium usually takes 3 to 4 months. The clinician should remember that considerable individual variation occurs in response to therapy; therefore it is impossible to check the serum calcium concentration too frequently.

237.1.17.4

Vitamin D Resistance

Occasionally, dogs (but more often cats) seem resistant to vitamin D in tablet form. This problem is usually resolved by using the liquid form of dihydrotachysterol or by using oral or parenteral calcitriol. It is not

common for dihydrotachysterol to begin to have an effect within the first 24 hours of therapy. Rather, vitamin D gradually takes effect during the first several days of therapy and almost always within 4 to 7 days of the first dose.

237.1.18 Pathology

Abnormal, autonomously functioning parathyroid glands from humans, dogs, and cats have been characterized histologically as adenoma, carcinoma, and hyperplasia. Controlled studies of histologic interpretations by pathologists have shown that it is difficult to consistently distinguish adenoma from hyperplasia and that nonmalignant parathyroid tissue may, in some cases, have many of the histologic features of malignancy.[3] Thus histologic classification of parathyroid disease depends, to some degree, on gross features observed during surgery. The surgeon determines the number, size, and appearance of normal versus abnormal glands. The pathologist then determines whether removed tissue is parathyroid. Single-gland involvement (adenoma, carcinoma, or hyperplasia) occurs in about 80% of hyperparathyroid humans and multiple-gland involvement ("hyperplasia") in about 20%.[48,66] It appears that single-gland involvement occurs in about 90% of dogs with PHPTH and multiple glands (almost always two but not more than two) occurs in about 10%. The diagnosis of carcinoma is based on a combination of gross appearance, histology, and, ultimately, biologic behavior of the lesion. Less than 2% of autonomously secreting parathyroid glands in humans are malignant.[67] In dogs, about 5% to 10% of dogs have been assigned the diagnosis of carcinoma. Regardless of the histologic diagnosis, no dog with distant metastasis has been recognized in our of 187 cases, and recurrence rate (10%) is similar, regardless of the histologic diagnosis.

237.1.19 Prognosis

The prognosis in dogs with PHPTH is excellent. With proper monitoring and appropriate supplementation, hypocalcemia may occur after therapy but should be treatable, transient, and should not alter the prognosis. About 33% of the dogs developed clinically significant hypocalcemia after treatment. The routine use of vitamin D (dihydrotachysterol or calcitriol) and calcium supplementation has dramatically decreased the incidence of tetany. Clinicians should avoid overdosing vitamin D, because renal damage is much more likely in this situation than in dogs with PHPTH.

237.2 PRIMARY HYPERPARATHYROIDISM IN CATS

237.2.1 Differential Diagnosis for Feline Hypercalcemia

It is fair to state that, in general, the same differential diagnoses for hypercalcemia in dogs applies to cats. In a study of 71 hypercalcemic cats, their mean age at the time of diagnosis was about 9 years and their mean serum total calcium concentration was 12.2 (lower than hypercalcemic dogs). Anorexia and lethargy were the most common clinical signs (70%). Vomiting, diarrhea, or constipation were observed in 27% of the cats; polyuria, polydipsia, or both were observed in 24%; and urinary signs were observed in 23%. Neurologic signs were observed in 14%.[68]

Neoplasia was diagnosed in 30% of the cats. The most common cancers diagnosed included lymphoma and squamous cell carcinoma. Less common neoplasms included leukemia, osteosarcoma, fibrosarcoma, undifferentiated sarcoma, and bronchogenic carcinoma.[68,69] Renal failure was diagnosed in 25% of the cats, and half of those cats had urolithiasis. In a separate study, chronic renal failure in cats was usually associated

with total serum calcium concentrations within the reference range, whereas serum ionized calcium concentrations were low-normal to low.[70] Of cats with hypercalcemia, several had urolithiasis without renal failure. Six percent of the cats (four cats) had PHPTH and one had hypoadrenocorticism. Several cats had hyperthyroidism or diabetes mellitus, but it would not seem likely that either of these endocrine problems would contribute to hypercalcemia. Four cats (6%) had infectious or granulomatous disease (feline infectious peritonitis [FIP], toxoplasmosis, actinomyces, and cryptococcosis). Thus the differential diagnosis for hypercalcemia in cats is not dramatically different from that in dogs (see Box 237-1).[68,71] Other differential diagnoses (e.g., vitamin D toxicosis, other neoplastic conditions, various granulomatous diseases) should also be considered.

237.2.2 Idiopathic Hypercalcemia of Cats

Hypercalcemia is less common in cats than in dogs, but an increased frequency of hypercalcemia in cats has been observed in several geographically distinct veterinary centers since about 1990.[21,72,73] It is striking that this hypercalcemia has not been, thus far, explained. Veterinarians are identifying young, middle-aged, and old cats with mild to moderate hypercalcemia and no identifiable cause. Serum total calcium concentrations in some of these cats have been increased for years, often without clinical signs, but some have poor appetites, weight loss, and appear weak. Serum ionized calcium concentrations are also increased, sometimes out of proportion to the increase in total calcium concentration.[21]

Nephrocalcinosis or uroliths may be observed on radiographs or on abdominal ultrasonography in some hypercalcemic cats. It has been estimated that as many as 33% of cats with calcium oxalate urolithiasis have had hypercalcemia. Renal function (based on BUN and serum creatinine concentrations) is initially within reference ranges, but renal failure may develop in some cats. By definition, these cats have had no evidence of a neoplastic condition (including necropsy), and they are feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) negative. Serum PTH concentrations have been normal or low, PTHrP has not been detectable, and vitamin D concentrations have been within reference ranges. Venous blood gas analyses have not demonstrated significant abnormalities.[21] Exploratory surgery of the cervical region has not identified any abnormalities, and subtotal parathyroidectomy has failed to resolve the hypercalcemia. A change to high-fiber or to nonacidifying diets may be associated with transient improvement but also failed to permanently resolve the condition. Treatment with prednisone (usually 5 to 10 mg/cat/day) has resulted in long-term decreases in serum calcium concentrations in some but not all afflicted cats. Prednisone, regardless of the effect on serum calcium concentrations, has resulted in improved appetite and weight gain in some but not all cats.

1527 1528

237.2.3 Primary Hyperparathyroidism in Cats

In addition to 10 cats with PHPTH in our series, an additional nine cats with PHPTH have been reported. Thus, only 19 cats with this condition, as compared with a much larger number of similarly afflicted dogs. Seven cats in the author's group of 10 with hypercalcemia due to PHPTH were described in one report, reported four cats were described in one report, two in each of two reports and one in another separate report.[21,74–77] The mean age of these 19 cats was approximately 13 years (range: 8 to 20 years), and various breeds were represented. The most common clinical signs described by owners were anorexia, lethargy, and vomiting. Less common signs were constipation, polyuria, polydipsia, and weight loss. A parathyroid mass was palpable in at least 11 of the 19 cats. The presence of a palpable mass and the owner observations contrast

with those of dogs, in which none had a palpable cervical mass and polyuria, polydipsia, and muscle weakness are common.

The only consistent abnormality on CBC and serum biochemical profiles was hypercalcemia (Table 237-8). All afflicted cats had persistent increases in both serum total and ionized calcium concentrations. Several cats had cystic calculi, and a large percentage had abnormalities in BUN and serum creatinine concentrations, findings not typical of their canine counterparts. Cervical ultrasonography was described as “normal” in several cats, but others had visible masses that would be considered huge in a dog. Cervical ultrasonography on two cats revealed parathyroid masses measuring 4.5 × 2 × 1 cm in one cat and 1.7 × 1.1 × 1 cm in the other.[77] Serum PTH concentrations, when measured, ranged from within the reference range (0 to 4 pmol/L) to increased. In one cat, seven separate serum PTH samples were assayed with five results being within the reference range and two being increased.

Most of the 19 cats had surgery and had resolution of the PHPTH after extirpation of the abnormal tissue. It seems that tetany has not been described in any cat treated with surgery, although several became hypocalcemic and were treated with vitamin D and calcium. Of the nine cats we followed after surgery, all lived well beyond 1 year from surgery, although at 1.5 years, one had recurrence of hypercalcemia and at necropsy was demonstrated to have both a parathyroid adenoma and a parathyroid carcinoma. Histologic evaluation of tissue from 13 cats had demonstrated parathyroid adenomas, three had carcinomas, two had hyperplasia (involving all four glands), and one had bilateral cystadenomas.

237.3 HYPOPARATHYROIDISM AND HYPOCALCEMIA

237.3.1 Background

Several historic landmarks in the understanding of parathyroid physiology, maintenance of homeostasis, and calcium regulation are significant with respect to hypocalcemia. Rickets (hypovitaminosis D) was first described in 1645. More than 200 years later (1884), an association was made between thyroidectomy in dogs and cats and the development of clinical hypocalcemia (tetany). In 1891, Gley proved that the parathyroids must be removed with the thyroids to produce tetany. Shortly thereafter, administration of calcium salts after parathyroidectomy was demonstrated to prevent tetany.

237.3.2 Pathophysiology

237.3.2.1 Initial Physiologic Alterations

Cessation of parathyroid function leads to a decrease in serum calcium concentration and an increase in plasma phosphate concentration. Urinary calcium and phosphate excretion diminishes. These changes are due to loss of PTH effects on mobilization of calcium and phosphate from bone, renal retention of calcium, enhanced renal excretion of phosphate, and increased absorption of calcium and phosphate from intestine.

237.3.2.2 Neuromuscular Activity

Ionized calcium is involved in the release of acetylcholine during neuromuscular transmission. Calcium is essential for muscle contraction, and it stabilizes nerve cell membranes by decreasing their permeability to sodium. Calcium's role as a membrane stabilizer is most obvious during severe hypocalcemia. When the extracellular concentration of calcium ion declines to subnormal levels, the nervous system becomes progressively more excitable owing to increased neuronal membrane permeability. Nerve fibers begin to discharge spontaneously, initiating impulses to peripheral skeletal muscles, where they elicit contractions. Consequently, hypocalcemia causes tetany. Dogs with untreated hypoparathyroidism have serum calcium concentrations consistently below 6.5 mg/dL. The onset of clinical tetany, however, is not entirely predictable.

In hypocalcemic dogs, “latent” tetany probably occurs. Owners mention that sudden excitement, activity, or petting unpredictably causes sporadic muscle cramping, lameness, facial rubbing, pain, irritability, or aggressive behavior. The nontetanic, severely hypocalcemic pet is often described by the owner as having a change in personality. Such signs are vague, but after hypocalcemia is diagnosed, the clinical signs are consistent with those of an animal in latent tetany. The various disturbances are completely and quickly reversible with therapy.

237.3.3 Clinical Features of Naturally Occurring Hypoparathyroidism—Dogs

237.3.3.1 Signalment

In reviewing the records of dogs in our series with naturally occurring primary hypoparathyroidism, the youngest dog was diagnosed at 6 weeks of age, the oldest was 13 years (average was 4.8 years), and 65%

were female.[78] The breeds most frequently identified as having primary hypoparathyroidism were poodles, miniature schnauzers, retrievers, German shepherds, and terriers.

237.3.3.2 Anamnesis

237.3.3.2.1 Duration of illness

The clinical course usually begins with an abrupt onset of intermittent neurologic or neuromuscular disturbances. Signs may be initiated or worsened by excitement or exercise. Signs associated with hypocalcemia had been observed for only 1 day in some dogs and for as long as 2 years in others. Many had been diagnosed and treated for nonspecific seizure disorders without the benefit of pretreatment laboratory testing. Most owners reported that their pets were "always" tense or nervous. Intense facial rubbing with the paws or on the ground was commonly observed but not usually mentioned by owners until specifically questioned. Additional signs included cramping and tonic spasm of leg muscles. Focal muscle twitching, generalized tremors, fasciculations, or trembling was frequently observed, as was a stiff, stilted, hunched, or rigid gait.

237.3.3.2.2 Seizures

Grand mal convulsions have been observed in 80% of dogs with primary hypoparathyroidism. Some of this seizure activity was atypical because there was no loss of consciousness and the dogs were not incontinent during the episode.[79] More than 80% of these dogs were observed, by a veterinarian, to have seizures or to be "in tetany." This represents a much higher incidence of veterinarian-witnessed neuromuscular signs than expected with most seizure disorders. The neuromuscular problems became so severe that several dogs, although not having seizures, were not able to stand or walk. Seizure episodes were as brief as 20 to 90 seconds and rarely lasted more than 30 minutes. Most, but not all, generalized seizures spontaneously abated.

237.3.3.2.3 Facial rubbing

More than 60% of the dogs in our series were observed to paw or rub violently at their muzzles, eyes, and ears, as well as rubbing their muzzles on the ground. These signs are thought to result from the pain associated with masseter and temporal muscle cramping caused by the hypocalcemia or from a "tingling" sensation around the mouth. Classic signs of hypocalcemia in humans include paresthesias—numbness and tingling that often occur around the mouth, in the tips of fingers, and sometimes in the feet.

237.3.3.3 Physical Examination

Other than signs related to hypocalcemia, dogs with primary hypoparathyroidism have no classic abnormalities on physical examination. A few dogs were thin, and several growled when examined. Retrospectively, the growling dogs were in pain or were anticipating that handling would result in pain because, after resolution of hypocalcemia, each became friendly. Cardiac abnormalities were apparent in about 40% of dogs on initial examination. These abnormalities consisted of paroxysmal tachyarrhythmias and muffled heart sounds with weak pulses. About half of the dogs appeared to be extremely tense, with splinted abdomens and stiff gaits. A smaller number had generalized muscle fasciculations, fever, or both.

Almost 50% had generalized seizures during their initial examination, and more than 80% had at least one convulsion during the initial 48 to 96 hours of hospitalization.

237.3.4 Clinical Features of Naturally Occurring Hypoparathyroidism—Cats

The clinical features of eight cats reported in the literature to have naturally occurring hypoparathyroidism are much like those reported in dogs. The clinical course for each cat was characterized by an abrupt or gradual onset of intermittent neurologic or neuromuscular disturbances that included focal or generalized muscle tremors, seizures, ataxia, stilted gait, disorientation, and weakness. Other commonly observed abnormalities included lethargy, anorexia, panting, and raised nictitating membranes.[80]

237.3.5 Diagnostic Evaluation—Dogs and Cats

237.3.5.1 Serum Calcium and Phosphate Concentrations

Severe hypocalcemia was a serendipitous finding in each of the dogs and cats with primary natural hypoparathyroidism (Table 237-9). Because therapy for hypocalcemia was quickly instituted, each animal had its serum calcium concentration monitored three to five times during the first 72 hours of hospitalization. In no dog or cat was the serum calcium concentration greater than 6.5 mg/dL until the therapy began to have an effect. Each dog and cat also had a serum phosphorus concentration higher than 1529
its calcium concentration, and all had normal BUN concentrations. 1530
The absence of an *absolute* hyperphosphatemia in some of dogs can be explained in part by the broad reference range provided by veterinary laboratories. No other abnormal laboratory findings were common.

237.3.5.2 Electrocardiogram

Hypocalcemia prolongs the duration of the action potential in cardiac cells. The findings most consistent with hypocalcemia included deep, wide T waves; prolonged Q-T intervals; and bradycardia. No obvious ECG findings could explain the arrhythmias, weak pulses, or muffled heart sounds that were noted on several physical examinations.

237.3.5.3 Serum Parathyroid Hormone Concentration

Undetectable serum PTH concentrations in animals that are severely hypocalcemic confirm the diagnosis of primary hypoparathyroidism, assuming that the assay used is reliable and validated. Serum PTH concentrations may be detectable as “low-normal” in some animals with hypoparathyroidism if the assay used is quite sensitive. However, a low-normal or low value would not be “normal” in a hypocalcemic animal that has healthy parathyroid glands.

237.3.6 Differential Diagnosis for Hypocalcemia

The differential diagnoses for hypocalcemia are presented in Box 237-6 and Figure 237-10.

237.3.6.1 Parathyroid-Related Hypocalcemia

Naturally occurring hypoparathyroidism is a rare condition in dogs and cats. Iatrogenic primary hypoparathyroidism has been recognized in dogs and cats after thyroid, parathyroid, or other surgeries of the neck. Magnesium deficiency can cause hypocalcemia. Severe hypomagnesemia in humans can result in a condition characterized by being refractory to PTH or it inhibits synthesis or secretion of PTH.

1531

237.3.6.1.1 Box • 237-6 Differential Diagnosis of Hypocalcemia

- Parathyroid-related hypocalcemia
  - Primary hypoparathyroidism
    - Destruction of glands
      - Immune-mediated process
      - Iatrogenic: surgical complication
      - Any disease in neck causing damage
    - Idiopathic atrophy (autoimmune process?)
  - Pseudohypoparathyroidism
- Chronic renal failure
- Hypoalbuminemia
- Acute pancreatitis
- Puerperal tetany (eclampsia)
- Intestinal malabsorption syndromes

- Nutritional secondary hyperparathyroidism (rare)
- Anticovulsant therapy
- Acute renal failure
- Ethylene glycol toxicity
- Phosphate-containing enemas
- Miscellaneous diagnoses
  - Laboratory error
  - Use of EDTA-anticoagulated blood
  - Vitamin D deficiency
  - Transfusion using citrated blood
  - Soft tissue trauma
  - Medullary carcinoma of the thyroid
  - Primary and metastic bone tumors
  - Cancer chemotherapy

237.3.6.2 Acute Renal Failure and Ethylene Glycol Toxicity

Acute renal failure, such as occurs with urethral obstruction, ureter obstruction, or ethylene glycol poisoning, can result in abrupt and severe increases in serum phosphate concentration. An acute increase in serum phosphate concentration causes a reduction in serum calcium concentration. This hypocalcemia may be exaggerated in acute renal failure, because the rapid progression of these disturbances blunts compensatory mechanisms. Cats with ureteral or urethral obstruction and hyperphosphatemia often have associated hypocalcemia, hyperkalemia, azotemia, and sometimes seizures.[39] Ethylene glycol intoxication

can cause severe renal failure, acidosis, and death. The metabolites of this toxin can chelate serum calcium ions and cause tetany.

237.3.6.3 Chronic Renal Failure, Hypoalbuminemia, and Pancreatitis

Chronic renal failure is an extremely common disorder in dogs and cats. This condition is most commonly associated with increases in serum phosphate concentrations with concurrent normal serum calcium concentrations. However, either hypocalcemia or hypercalcemia may occur in animals with chronic renal failure. Serum ionized calcium concentrations from animals with renal failure are often low-normal to low.[81]

Reductions in total serum protein, serum albumin concentrations, or both are encountered in a variety of disorders. Decreased circulating albumin causes a decrease in the protein-bound fraction of circulating calcium. However, ionized calcium concentrations are typically normal. Hypocalcemia, when it occurs in dogs with acute pancreatitis, is usually mild and subclinical. Coexisting pancreatitis and acidosis, which is commonly present, increases the amount of serum calcium that is ionized and further reduces any chance of tetany.

237.3.6.4 Puerperal Tetany (Eclampsia)

Eclampsia is an acute life-threatening condition caused by extreme hypocalcemia in lactating bitches and queens. In most studies, dogs with eclampsia are severely hypocalcemic (< 6.5 mg/dL). Eclampsia is most common in small dogs, being less common in cats and large dogs.

237.3.6.5 Nutritional Secondary Hyperparathyroidism

Dogs and cats fed diets containing low calcium-to-phosphorus ratios, such as beef heart or liver, can develop severe mineral deficiencies. Dietary calcium deficiency results in transient decreases in serum calcium concentration, inducing increased PTH secretion, reduction in bone mass as calcium is removed from bone to replace that lacking in the diet, and diffuse skeletal disorders. Skeletal problems include bone pain and pathologic fractures and are the result of the normal physiologic processes that maintain serum mineral homeostasis. Usually these animals have normal serum concentrations of both calcium and phosphorus. Occasionally, such an animal is hypocalcemic. These dogs and cats should be treated by providing balanced diets and restricting activity until skeletal remodeling is complete. Diagnosis is based on recognizing skeletal disorders in a dog or cat given an improper diet.

237.3.6.6 Miscellaneous Causes of Hypocalcemia

Commercial phosphate-containing enemas may result in acute, marked hyperphosphatemia and, subsequent hypocalcemia after colonic adsorption of the enema solution, especially when administered to dehydrated cats with colonic atony and mucosal disruption. These rare problems include laboratory error, vitamin D deficiency, use of citrated blood, trauma, medullary carcinoma of the thyroid, primary and metastatic bone tumors, and some forms of chemotherapy.

237.3.7 Therapy for Hypoparathyroidism and Hypocalcemia

237.3.7.1 Emergency Therapy for Tetany

When treating a seizing animal without a specific diagnosis, diazepam is the initial drug usually chosen to control the signs. However, if this treatment fails or if a diagnosis is still not obvious, blood should be drawn for glucose, calcium, and any other parameter that may lead to a definite diagnosis. Hypocalcemic tetany improves after replacement of calcium, although these animals usually respond to diazepam. Calcium should be administered intravenously, slowly to effect. The dose is 1 to 1.5 mL/kg or 5 to 15 mg/kg, administered slowly over a 10-to 30-minute period. Calcium gluconate, as a 10% solution (Table 237-10), is recommended because, unlike calcium chloride, calcium gluconate extravasating outside a vein is not caustic. Calcium chloride can cause not only tremendous tissue sloughing but also calcinosis cutis.[82] Electrocardiographic monitoring is advisable. If bradycardia, premature ventricular complexes, or shortening of the Q-T interval is observed, the IV infusion should be briefly discontinued.[40] This rapid emergency therapy is invariably successful, with a response noted within minutes of initiating the infusion. However, the final dose needed to control tetany is somewhat unpredictable. The recommendation is to use the suggested dose (in mg/kg) as a guideline and patient response as the definitive factor in determining the volume administered. Infusion of calcium-rich fluids should proceed with caution in a dog or cat with hyperphosphatemia. The additional calcium could result in mineralization of soft tissue causing further damage to the kidneys in animals with coexisting renal insufficiency or failure.[39]

237.3.7.2 Fever

Fever frequently accompanies tetany. It is not unusual to have a dog or cat in tetany with a rectal temperature above 105° F. There is often temptation to treat both the hypocalcemia and the fever (with ice or alcohol baths; parenteral drugs). It is recommended, however, that with institution of calcium therapy, one should monitor but not treat fever. Fever usually dissipates rapidly with control of tetany. Additional measures to lower body temperature may result in hypothermia and the development of shock.

Calcium chloride (IV)	10% solution, 10-mL ampule	27.2 mg Ca/mL	Not recommended
Calcium gluceptate (calcium glucoheptonate) (IV, IM)	22% solution, 5 mL ampule	18 mg Ca/mL	—

Ca, Calcium; *P,* phosphate; *IV,* intravenous; *SQ,* subcutaneous; *IM,* intramuscular.

237.3.8 Post-Tetany Short-Term Maintenance Therapy

237.3.8.1 Subcutaneous Calcium

Once tetany has been controlled with intravenous bolus calcium gluconate, administration of subcutaneous calcium is effective, simple, and inexpensive. A dose of calcium gluconate equal to that needed for the initial control of tetany can be given subcutaneously every 6 to 8 hours. The calcium gluconate should be diluted in an equal volume of saline. This protocol has effectively supported serum calcium concentrations while waiting for oral vitamin D to take effect. It is a procedure that can be easily taught to owners, further decreasing their expense.

After serum calcium concentrations have been maintained for 48 hours, the frequency of subcutaneous injections should be decreased from every 6 to every 8 hours. If serum calcium concentrations remain stable for the ensuing 48 to 72 hours, the calcium can be tapered to twice daily. This protocol is continued until parenteral calcium has been completely discontinued. Obviously, the tapering process in each animal may not be this smooth, because response to oral Vitamin D therapy is variable. Ideally, the serum calcium concentration should be maintained above 8 mg/dL. Serum calcium concentrations below 8 mg/dL indicate the need to increase the dose of parenteral calcium, serum calcium concentrations of 8 to 9 mg/dL suggest that the current dose should be maintained, and values greater than 9 mg/dL suggest the need to reduce the parenteral calcium dose.

237.3.8.2 Repeating Intravenous Bolus

One alternative to the management of hypocalcemia in the immediate post-tetany period would be intravenous calcium by bolus, as needed. This procedure is not recommended except as required in an emergency.

237.3.8.3 Calcium Supplementation in a Continuous Intravenous Solution

Calcium can be administered slowly, intravenously, via an infusion solution. Calcium gluconate is administered in the infusion to attain a dose of 60 to 90 mg/kg per day (approximately 2.5 mL/kg of 10% calcium gluconate added to the infusion solution and administered every 6 to 8 hours). This calcium should not be added to a bicarbonate-containing solution because of potential precipitation problems. Serum calcium concentrations should be monitored once or twice daily, with the rate of infusion adjusted as needed.

237.3.9 Maintenance Therapy

237.3.9.1 Vitamin D

The need for vitamin D therapy is usually permanent in dogs and cats with primary naturally occurring parathyroid gland failure. Calcium supplementation, however, can often be tapered and then stopped, because dietary calcium is sufficient to meet the needs of the animal. Supplemental calcium in conservative doses, however, ensures that vitamin D, which raises serum calcium by promoting its intestinal absorption, has a substrate upon which to function. Iatrogenic hypoparathyroidism in cats that have had neck surgery is often transient, and lifelong therapy is not always needed. In contrast to treating tetany, when the immediate goal is to avoid recurrence of neuromuscular signs, the aim of long-term therapy is maintaining the serum calcium concentration at mildly low to low-normal concentrations (8 to 9.5 mg/dL). These calcium concentrations are above the level of risk for clinical hypocalcemia and below that which might be associated with hypercalciuria (risk of calculi formation) or severe hypercalcemia and hyperphosphatemia (risk of nephrocalcinosis and renal failure).

237.3.9.2 Vitamin D_2 (Ergocalciferol)

It is recommended that dihydrotachysterol or calcitriol be used for long-term treatment. For some owners, *1533*
however, these drugs are too expensive. Vitamin D_2 can be given as a less-than-ideal but less-expensive *1534*
alternative. It is a widely available drug (Table 237-11). Initially, large doses are required to induce normocalcemia. Dogs and cats can be given 4000 to 6000 U/kg once daily. These doses are needed to offset the decreased biologic potency of this product in hypoparathyroid animals. Additionally, large doses are required to saturate fat depots, because vitamin D is a fat-soluble vitamin. Effect of the medication is usually obvious 5 to 14 days after beginning therapy. Parenteral calcium can usually be discontinued 1 to 5 days after starting oral treatment.

Table • 237-11 Vitamin D Preparations

PREPARATION	DOSE FORM	COMMERCIAL NAME (MANUFACTURER)	DAILY DOSE	TIME REQUIRED FOR MAXIMAL EFFECT	TIME REQUIRED FOR TOXICITY RELIEF
Vitamin D_2 (ergocalciferol)	Capsules 25,000 U 50,000 U	Calciferol (Rorer)	Initial: 4000–6000 U/kg/day	5–21 days	1–18 weeks
		Drisdol (Winthrop-Breon)			
		Deltalin Lilly			
	Oral syrup 8000 U/mL	Drisdol (Winthrop-Breon)	Maintenance: 1000–2000 U/kg once daily-once weekly		
	IM injectable 50,000 U/mL	Calciferol (Rorer)			
		Vitadee (Gotham)			
Dihydrotachysterol	Tablets 0.125 mg 0.2 mg 0.4 mg	Dihydrotachysterol (Phillips-Roxane)	Initial: 0.02–0.03 mg/kg/day	1–7 days	1–3 weeks
	Capsules 0.125 mg	Hytakerol (Winthrop-Breon)	Maintenance: 0.01–0.02 mg/kg q24-48h		
	Oral solution 0.25 mg/mL	Hytakerol (Winthrop-Breon)			
Vitamin D_1 (calcitriol)	Capsules 0.25 µg 0.5 µg	Rocaltrol (Roche) (also generic)	Approximate: 0.03–0.06 µg/kg/day	1–4 days	24 hours-2 weeks
	Vitamin D3 injectable 1.0 µg/ml	Calcijex (Abbott Laboratories)	Approximate: 0.02 µg/kg/day		1 to 7 days/week

Dogs and cats receiving vitamin D_2 should be hospitalized, ideally, until the serum calcium concentration remains between 8 and 10 mg/dL without parenteral support. At this time, the pet can be returned to the owner and vitamin D given every other day. Serum calcium concentrations should be monitored weekly, with the vitamin D dose adjusted to maintain a serum calcium concentration of 8 to 9.5 mg/dL. The aim of therapy is to avoid hypocalcemic tetany, but the most common problem with therapy is induction of hypercalcemia. Once the pet appears stable, monthly rechecks are strongly advised for 6 months and then every 2 to 3 months, thereafter.

237.3.9.3 Dihydrotachysterol

The advantages of dihydrotachysterol versus vitamin D_2 are that it raises the serum calcium concentration faster (1 to 7 days) and its effects dissipate faster when administration is discontinued. Therefore the veterinarian has more control over the therapy. Dihydrotachysterol is readily available and is more expensive than vitamin D_2 (see Table 237-11). This product is more potent than vitamin D_2, 1 mg of dihydrotachysterol being equivalent to 120,000 U of vitamin D_2. Dihydrotachysterol is initially given at a dose of 0.03 mg/kg per day for several days or until effect is demonstrated, then 0.02 mg/kg per day for 2 days, and finally 0.01 mg/kg per day. As suggested with the less potent vitamin D, the pet should remain hospitalized until the serum calcium concentration remains stable between 8 and 9.5 mg/dL for several days. we have seen cats and dogs that appeared to be resistant to the tablet and capsule forms of this drug (0.125, 0.25, 0.4 mg) but responded readily to the liquid (0.25 mg/mL). Rechecks of the serum calcium

concentration on a weekly basis allow dose adjustment while avoiding prolonged hyper-or hypocalcemia. As with vitamin D_2, long-term rechecks at two to three month intervals are strongly encouraged.

Hypercalcemia (> 12 mg/dL) should be treated by discontinuing vitamin D therapy and, depending on the severity of the clinical signs and biochemistry abnormalities, possibly initiating intravenous fluids, furosemide, corticosteroids, or a combination of these treatments. The period from stopping dihydrotachysterol to noting a fall in the serum calcium concentration is between 4 and 14 days, a much briefer period than that seen with vitamin D_2.

237.3.9.4 1,25-Dihydroxyvitamin D (Calcitriol)

This drug offers the advantages of rapid onset of action (1 to 4 days) and short half-life (less than 1 day). If hypercalcemia results from overdose, it can be rapidly corrected by discontinuing the drug. Because 1,25-dihydroxyvitamin D does not require activation by the kidney, physiologic doses should readily maintain normocalcemia in a pet with hypoparathyroidism, a state in which renal 1-alpha-hydroxylase activity is low. In contrast, relatively larger pharmacologic doses of vitamin D_2 or dihydrotachysterol must be used to overcome this block in renal 1-hydroxylation. We have not used this drug for chronic maintenance therapy of dogs or cats with primary hypoparathyroidism.

237.3.10 Calcium

237.3.10.1 Initial Approach to Oral Calcium

Dietary calcium must be adequate when treating hypoparathyroidism, because the primary mode of therapy is the administration of vitamin D, which acts to increase absorption of calcium present in the intestinal lumen. Usually sufficient calcium is found in commercial pet foods. However, to avoid the catastrophic problems of hypocalcemia, especially early in the course of therapy, oral calcium supplementation is strongly recommended. Oral calcium and vitamin D therapy should be started while tetany is being controlled with parenteral calcium. After 24 to 96 hours, the parenteral calcium administration can often be discontinued while oral therapy is maintained. In this manner, smooth, continuous control is achieved.

1534 1535

237.3.10.2 Calcium Supplements

Supplements can be provided by administering calcium as the gluconate, lactate, chloride, or carbonate salt. Each have disadvantages. Calcium gluconate and lactate tablets contain relatively small quantities of elemental calcium, so relatively large numbers of tablets must be given. Calcium chloride tablets contain large quantities of calcium but tend to produce gastric irritation. Calcium carbonate tablets also contain large quantities of calcium but tend to produce alkalosis, which may aggravate hypocalcemia. Calcium carbonate is 40% calcium. One gram yields 20 mEq of calcium, and gastric acid converts the calcium carbonate to calcium chloride. Calcium lactate is 13% calcium, and 1 g yields 6.5 mEq. Calcium gluconate contains 9% calcium, and 1 g yields 4.5 mEq. Obviously, numerous calcium preparations are available (Table 237-11). Calcium carbonate is the preparation of choice in treating hypoparathyroid humans because of its high percentage of calcium, ready availability in drugstores in the form of antacids, low cost, and lack of gastric irritation.[2] No specific research is available to support recommendations for use of this drug in dogs and cats, although the author's success with calcium carbonate has been excellent.

237.3.11 Treatment Protocol

In cats the dose of calcium is approximately 0.5 to 1 g per day, in divided doses. In dogs, the dose is usually 1 to 4 g per day, in divided doses. These recommendations are approximate, and the primary therapy that determines stability of the serum calcium concentration is the use of vitamin D. As the vitamin D dose reaches a steady level, the dose of calcium can be gradually tapered over 2 to 4 months. This method of treatment avoids unnecessary therapy, considering that dietary calcium should be sufficient to supply the needs of the pet and should decrease the demands of treatment placed on the owner. It must be emphasized that the ideal serum calcium concentration in these animals is 8 to 9.5 mg/dL. Concentrations above 10 are too high, are unnecessary in avoiding tetany, and increase the likelihood of unwanted hypercalcemia.

237.3.12 Parathyroid Histology in Primary Hypoparathyroidism

Animals have been classified as having idiopathic hypoparathyroidism when the clinician finds no evidence of trauma, malignant or surgical destruction, or other obvious damage to the neck or parathyroid glands. The glands are difficult to locate visually and are microscopically atrophied. Approximately 60% to 80% of the glands are replaced by mature lymphocytes, occasional plasma cells, extensive degeneration of chief cells, and fibrous connective tissue. Chief cells are randomly isolated in multiple small areas or bands at the periphery. In the early stages, infiltration of the gland with lymphocytes and plasma cells occurs, with nodular regenerative hyperplasia of remaining chief cells. Later, the parathyroid gland is completely replaced by lymphocytes, fibroblasts, and neocapillaries, with only an occasional viable chief cell. The final interpretation is one of lymphocytic parathyroiditis.[83,84]

237.3.13 Prognosis

The prognosis with primary hypoparathyroidism is dependent, for the most part, on the dedication of the owner and, to a lesser extent, on the experience of the veterinarian. With proper therapy, the prognosis is excellent. Twenty-one of 25 dogs that we observed, lived more than 5 years. However, proper management requires close monitoring of the serum calcium concentration, ideally once every one to three months once the pet is stabilized. The more frequent the rechecks, the better chance the pet has of avoiding extremes in serum calcium concentrations. The chance for a normal life expectancy is excellent with proper care.

238 CHAPTER • 238 Hypothyroidism

J. Catherine

R. Scott-Moncrieff

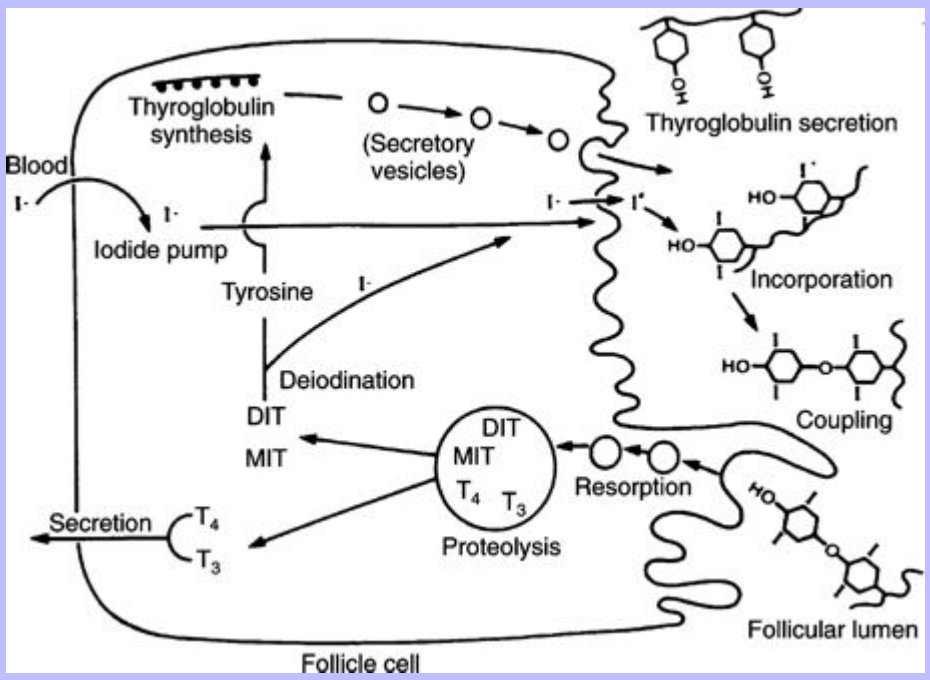
Lynn Guptill-Yoran

Hypothyroidism is the result of decreased production of thyroxine (T_4) and triiodothyronine (T_3) by the thyroid gland. Naturally occurring hypothyroidism is common in dogs but extremely rare in cats.

238.1 PHYSIOLOGY AND METABOLISM

Thyroid hormones are iodine-containing amino acids synthesized in the thyroid gland (Figure 238-1). All circulating T_4, but only 20% of T_3, is derived from the thyroid gland. The majority of T_3 is derived from extrathyroidal enzymatic 5′-deiodination of T_4. In the blood, more than 99% of T_4 and T_3 are bound to plasma proteins, with T_4 more highly bound than T_3. In the dog, the thyroid binding proteins are thyroid hormone-binding globulin (TBG), transthyretin, albumin, and apolipo-proteins, with most T_4 bound to TBG. Dogs have lower avidity of thyroid hormone binding to serum proteins than do humans, which results in lower total serum concentrations of T_4 and T_3, higher free hormone concentrations, and more rapid clearance rates.

Figure 238-1 Synthesis of thyroid hormones. The follicular cells of the thyroid gland concentrate iodide, which diffuses down a gradient into the colloid. Thyroglobulin is synthesized within thyroid follicular cells and secreted into the colloid. Iodide is oxidized and bound to tyrosine residues on the thyroglobulin molecule by thyroid peroxidase. Iodinated tyrosine residues (monoiodotyrosine [MIT] and diiodotyrosine [DIT]) within the thyroglobulin molecule then undergo oxidative condensation to form the iodothyronines (T_3 and T_4), which remain bound to thyroglobulin until secreted. Thyroglobulin is ingested by endocytosis from the colloid; the peptide bonds between the iodinated residues and the thyroglobulin are hydrolyzed; and MIT, DIT, T_4, and T_3, are released into the cytoplasm. MIT and DIT are deiodinated and the iodine is recycled, while T_4 and T_3 are released into the bloodstream. (From Mountcastle VB: *Medical physiology*, ed 14, vol 2. St Louis, 1980, Mosby.)



Only free hormone enters cells to produce a biologic effect or a negative feedback effect on the pituitary and hypothalamus. T_3 enters cells more rapidly, has a more rapid onset of action, and is three to five times more

potent than T_4. Thyroid hormones bind to receptors in the nuclei; the hormone receptor complex binds to DNA and influences the expression of a variety of genes coding for regulatory enzymes.

Thyroid hormone synthesis and secretion are regulated primarily by changes in the circulating concentration of pituitary thyrotropin (TSH) (Figure 238-2). Thyroid hormones are metabolized by progressive deiodination. Outer-ring deiodination of T_4 produces T_3, whereas inner-ring deiodination results in formation of biologically inactive reverse T_3 (rT_3). Deiodination is regulated by the relative activity of different deiodinase enzymes and is an important regulatory step in thyroid hormone metabolism. Thyroxine and T_3 are both concentrated in the liver and secreted in the bile.

Thyroid hormones have a wide variety of physiologic effects. Thyroid hormones increase the metabolic rate and oxygen consumption of most tissues, with the exception of the adult brain, testes, uterus, lymph nodes, spleen, and anterior pituitary. Thyroid hormones have positive inotropic and chronotropic effects on the heart. They increase the number and affinity of beta-adrenergic receptors, enhance the response to catecholamines, and increase the proportion of alpha-myosin heavy chains. Thyroid hormones have catabolic effects on muscle and adipose tissue, stimulate erythropoiesis, and regulate both cholesterol synthesis and degradation. Thyroid hormones are also essential for the normal growth and development of the neurologic and skeletal systems.

238.2 CANINE HYPOTHYROIDISM

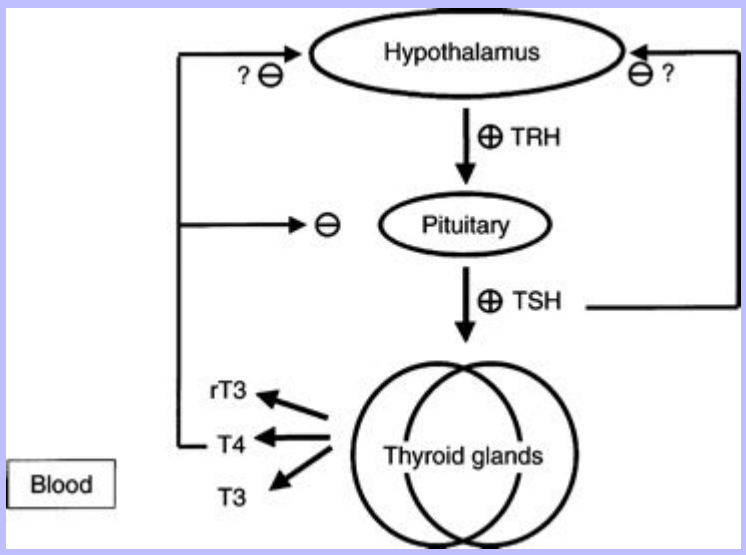
238.2.1 Pathogenesis

Hypothyroidism may result from dysfunction of any part of the hypothalamic-pituitary-thyroid axis (see Figure 238-2). Most acquired canine hypothyroidism is the result of lymphocytic thyroiditis or idiopathic thyroid atrophy.

Approximately 50% of canine primary hypothyroidism is due to lymphocytic thyroiditis.[1] Grossly, the thyroid gland may appear normal or atrophic. There is multifocal or diffuse infiltration of the thyroid gland by lymphocytes, plasma cells, and macrophages.[1] Remaining follicles are small, and lymphocytes, macrophages, and degenerate follicular cells may be found within vacuolated colloid. As thyroiditis progresses, parenchyma is destroyed and replaced by fibrous connective tissue.

Canine thyroiditis is believed to be immune-mediated[2], but the immunologic and molecular pathogenesis has not been well characterized. Antithyroglobulin antibodies are present in 36% to 50% of hypothyroid dogs[3–4], but whether these antibodies occur secondary to follicular cell damage from infiltrating T-cells, or are directly involved in the pathogenesis of thyroiditis is unclear. Thyroiditis is heritable in the beagle and the Borzoi.[5–7] The prevalence of antithyroglobulin antibodies varies significantly from breed to breed.[8]

Figure 238-2 Regulation of thyroid hormone concentrations. Thyroid hormone concentrations are controlled by the hypothalamic-pituitary-thyroid axis, which operates as a negative feedback loop. Thyrotropin (TSH) causes synthesis and release of T_4 and lesser amounts of T_3 from the thyroid gland. Intracellular T_3, derived from deiodination of T_4 within the pituitary gland, causes decreased TSH synthesis and secretion and is the main determinant of TSH concentration. Thyrotropin-releasing hormone (TRH), secreted by the hypothalamus, modulates TSH release from the pituitary gland. Increased thyroid hormone concentrations are also believed to decrease TRH synthesis and secretion. Hormones that inhibit TSH secretion include dopamine, somatostatin, serotonin, and glucocorticoids. TRH, prostaglandins, and alpha-adrenergic agonists increase TSH secretion.



In idiopathic follicular atrophy, there is loss of thyroid parenchyma and replacement by adipose connective tissue.[1] Degeneration of individual follicular cells occurs, with exfoliation of cells into the colloid. Because of the absence of fibrosis or inflammation it is unclear whether follicular atrophy is a distinct syndrome or the final result of thyroiditis.

Less commonly, hypothyroidism is caused by bilateral thyroid neoplasia or invasion of the thyroid by metastatic neoplasia.[9] Dogs with thyroid neoplasia remain euthyroid until at least 75% of the thyroid parenchyma has been destroyed. Lymphocytic thyroiditis has been identified as a risk factor for thyroid neoplasia.[5]

Secondary hypothyroidism (deficiency of TSH) is rarely described in dogs. Causes of acquired secondary hypothyroidism include pituitary malformations and pituitary neoplasia. Histologic changes observed in secondary hypothyroidism include flattening of follicular epithelial cells and distention of thyroid follicles with colloid.[10] Tertiary hypothyroidism (deficiency of thyrotropin releasing hormone [TRH]) has yet to be documented in the dog.

Congenital hypothyroidism (cretinism) is rarely diagnosed in dogs. Reported causes of congenital primary hypothyroidism include iodine deficiency, thyroid dysgenesis, and dyshormonogenesis.[11] Congenital hypothyroidism with goiter due to thyroid peroxidase deficiency was reported as an autosomal recessive trait in toy fox terriers.[12] A genetic test is available to detect carriers of the affected gene. Secondary congenital hypothyroidism due to apparent isolated TSH or TRH deficiency was reported in a family of young giant schnauzers and in a young boxer.[10,13] In both reports, central hypothyroidism was suspected because of increased T_4 secretion and increased uptake of ^{99m}Tc-pertechnetate after repeated administration of TSH. Congenital secondary hypothyroidism is also a feature of panhypopituitarism.

Iatrogenic causes of hypothyroidism include ^{131}iodine treatment, administration of antithyroid drugs, and surgical thyroidectomy. Because of the presence of accessory thyroid tissue, permanent hypothyroidism is rare after thyroidectomy.

238.2.2 Epidemiology

The reported prevalence of canine hypothyroidism is from 0.2% to 0.8%.[14–15] Mean age at diagnosis is 7 years, with a range of 0.5 to 15 years. Golden retrievers and Doberman pinschers are among the breeds reported to be at higher risk for hypothyroidism. Neutered males and females were reported in one study to be at increased risk for developing hypothyroidism compared with sexually intact animals[14]; however, in the most recent study of hypothyroid dogs in the United Kingdom there was no association with breed, gender, or neuter status.[15]

238.2.3 Clinical Signs

Because thyroid hormones influence the function of many organs, hypothyroidism is considered in the differential diagnosis of a wide range of problems. Clinical signs of hypothyroidism may be nonspecific and insidious in onset, and hypothyroidism is commonly misdiagnosed. Common clinical signs attributable to decreased metabolic rate include lethargy, mental dullness, weight gain, unwillingness to exercise, and cold intolerance.[14–15] Obesity occurs in approximately 40% of hypothyroid dogs, but most obese dogs suffer from overnutrition rather than hypothyroidism.

Dermatologic changes occur in 60% to 80% of hypothyroid dogs.[14–15] Common findings include dry scaly skin, changes in haircoat quality or color, alopecia, seborrhea (sicca or oleosa), and superficial pyoderma. Hyperkeratosis, hyperpigmentation, comedone formation, hypertrichosis, ceruminous otitis, poor wound healing, increased bruising, and myxedema may also occur. Alopecia is usually bilaterally symmetric and is first evident in areas of wear, such as the lateral trunk, ventral thorax, and tail. The head and extremities tend to be spared. The hair is often brittle and easily epilated, and loss of undercoat or primary guard hairs may result in a coarse appearance or a puppy-like haircoat. Fading of coat color may also occur, and failure of hair

regrowth after clipping is common. Signs of decreased metabolic rate in conjunction with dermatologic abnormalities should increase suspicion of hypothyroidism.

Hypothyroid dogs are predisposed to recurrent bacterial infections of the skin such as folliculitis, pyoderma, and furunculosis. *Malassezia* spp. infections and demodicosis are associated with hypothyroidism. Pruritus may occur with concurrent infection.

Myxedema (cutaneous mucinosis) is a rare dermatologic manifestation of hypothyroidism characterized by nonpitting thickening of the skin, especially of the eyelids, cheeks, and forehead. It is caused by deposition of hyaluronic acid in the dermis.[16] A rare complication of myxedema is cutaneous mucinous vesiculation.[17]

Female reproductive abnormalities attributed to hypothyroidism include prolonged interestrous interval, silent estrus, failure to cycle, spontaneous abortion, small numbers or low–birth-weight litters, uterine inertia, and weak or stillborn puppies; however, the evidence for this association is weak. Inappropriate galactorrhea apparently due to hyperprolactinemia has been reported in sexually intact hypothyroid bitches.[18] Male reproductive problems attributed to hypothyroidism include low libido, testicular atrophy, hypospermia, and azoospermia. However, a prospective study of six male beagles with ^{131}iodine-induced hypothyroidism showed no decrease in libido or sperm quality over a 2-year period.[19] Decreased testicular size, subfertility, or sterility were reported in association with thyroiditis and orchitis in a colony of beagles.[20]

Both the peripheral and central nervous systems may be affected by hypothyroidism. Peripheral neuropathy is the best documented neurologic manifestation.[21–22] Affected dogs have exercise intolerance, weakness, ataxia, quadriparesis or paralysis, deficits of conscious proprioception, and decreased spinal reflexes. Clinical signs resolve with *l*-thyroxine (T_4) supplementation. A subclinical myopathy also occurs in hypothyroid dogs.[23] Unilateral lameness reported in hypothyroid dogs may be a manifestation of generalized neuromyopathy.[24]

Dysfunction of multiple cranial nerves (facial, trigeminal, vestibulocochlear) and abnormal gait and postural reactions are also reported.[22,25] Hypothyroid dogs with vestibular deficits have abnormal brain stem auditory-evoked responses and some dogs also have electromyographic abnormalities of appendicular muscles. Clinical signs resolve with T_4 supplementation. Because dogs with vestibular disease may have resolution of clinical signs owing to compensation, a causal relationship is less clear.[22] Although laryngeal paralysis and megaesophagus have been reported in association with hypothyroidism, treatment of hypothyroidism does not consistently result in resolution of clinical signs, and a causal relationship has not been confirmed. Myasthenia gravis has been reported in association with hypothyroidism.[26] Concurrent hypothyroidism may exacerbate clinical signs of myasthenia gravis such as muscle weakness and megaesophagus.

Rarely, cerebral dysfunction occurs in hypothyroidism due to myxedema coma, atherosclerosis, or the presence of a pituitary tumor causing secondary hypothyroidism. Seizures, disorientation, and circling may occur due to severe hyperlipidemia or cerebral atherosclerosis.[27–28] In myxedema coma, profound mental dullness or stupor is accompanied by nonpitting edema, hypothermia with a lack of shivering, bradycardia, weakness, and inappetence.[29]

1537

1538

Abnormalities of the cardiovascular system such as sinus bradycardia, weak apex beat, low QRS voltages, and inverted T waves occur in hypothyroid dogs.[14] Reduced left ventricular pump function has also been

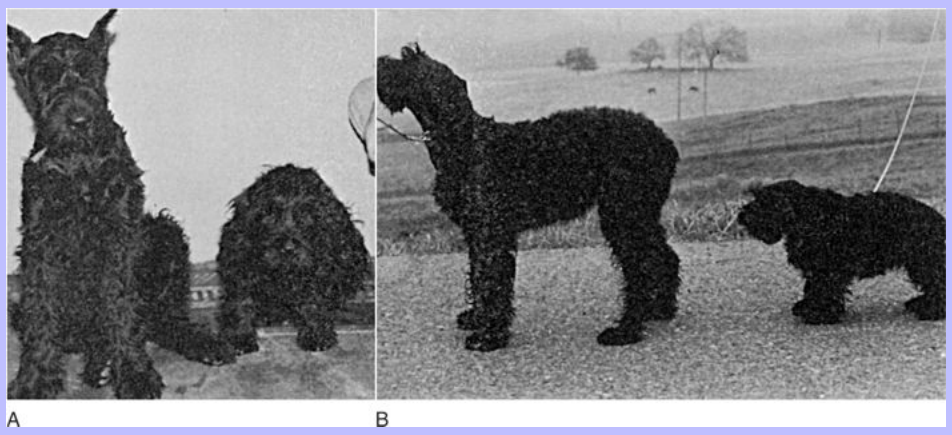
documented, and hypothyroidism may exacerbate clinical signs in dogs with underlying cardiac disease.[30] Although hypothyroidism rarely causes clinically significant myocardial failure in dogs, dilated cardiomyopathy and hypothyroidism may occur concurrently. A recent case report documented dramatic long-term improvement in cardiac function after treatment with T_4 in two Great Danes with concurrent dilated cardiomyopathy and hypothyroidism.[31]

Ocular abnormalities reported in canine hypothyroidism include corneal lipidosis, corneal ulceration, uveitis, lipid effusion into the aqueous humor, secondary glaucoma, lipemia retinalis, retinal detachment, and keratoconjunctivitis sicca, however a definite causal relationship has not been proven. Dogs with experimentally induced hypothyroidism did not develop ocular changes over a 6-month time period.[32]

Clinical signs of secondary hypothyroidism are similar to those of primary hypothyroidism, but clinical signs related to a deficiency of other pituitary functions may predominate, particularly if a pituitary neoplasm is present.

Congenital hypothyroidism results in mental retardation and stunted disproportionate growth due to epiphyseal dysgenesis and delayed skeletal maturation (Figure 238-3).[33] Affected dogs are mentally dull and have large, broad heads, short thick necks, short limbs, macroglossia, hypothermia, delayed dental eruption, ataxia, and abdominal distention.[10–13] Dermatologic findings are similar to those seen in the adult hypothyroid dog. Other clinical signs may include gait abnormalities, stenotic ear canals, sealed eyelids, and constipation. Affected puppies are often the largest in the litter at birth but start to lag behind their littermates within three to eight weeks. It is likely that many severely affected puppies die without a diagnosis in the first few weeks of life. Vertebral physeal fracture causing tetraparesis was reported in a dog with congenital hypothyroidism.[33]

Figure 238-3 Eight-month-old female giant schnauzer littermates. The dog on the left is normal, whereas the smaller dog on the right has congenital hypothyroidism (cretinism). Note the small stature; disproportionate body size; large, broad head; wide, square trunk; and short limbs in the cretin. (From Feldman EC, Nelson RW: *Canine and feline endocrinology and reproduction,* ed 2, Philadelphia, 1996, WB Saunders, p 83.)



238.2.4 Clinicopathologic Changes

Results of a hemogram, biochemical panel, and urinalysis often support a diagnosis of hypothyroidism and rule out other disorders. A mild nonregenerative anemia occurs in 30% of hypothyroid dogs.[14] Fasting hypercholesterolemia occurs in 75% of hypothyroid dogs, whereas hypertriglyceridemia occurs in up to 88%.[15] In rare cases hyperlipidemia may lead to atherosclerosis. Less common abnormalities include mild increases in alkaline phosphatase, alanine aminotransferase, and creatine kinase. Mild hypercalcemia has been reported in congenital hypothyroidism.

238.2.5 Hemostasis

Decreased plasma von Willebrand factor antigen (vWf:Ag) concentration was reported in hypothyroid dogs; however, studies have failed to demonstrate a relationship between vWf:Ag or factor VIII activity and thyroid hormone status.[34–36] Canine hypothyroidism is rarely associated with clinical bleeding, and platelet function and bleeding times are normal. Concentrations of vWf:Ag do not consistently increase during treatment of hypothyroid dogs with T_4.[35]

238.2.6 Polyendocrinopathies

Canine hypothyroidism may occur in association with other immune-mediated endocrine disorders such as hypoadrenocorticism and diabetes mellitus.[37–39] Hypothyroidism causes insulin resistance and may mask the classic electrolyte changes of hypoadrenocorticism.

238.2.7 Diagnosis of Hypothyroidism

238.2.7.1 Patient Selection

Appropriate patient selection is important in evaluation of thyroid function. The positive predictive value of diagnostic tests is highest when the prevalence of the disease is high. A complete history, physical examination and minimum database aid in identification of other diseases and determination of whether thyroid dysfunction is likely. Testing of healthy dogs prior to breeding or of obese dogs with no other clinical signs of thyroid disease increases the chance of false-positive test results.

1538

1539

238.2.7.2 Basal Thyroid Hormone Concentrations

Thyroid hormones commonly measured include total T_4 (TT_4), total T_3 (TT_3), and free T_4 (fT_4). Assays for free T_3 (fT_3) and reverse T_3 (rT_3) are less commonly used. Assays must be validated for the dog. Serum antibodies directed against T_3 and T_4 may interfere with thyroid hormone assays because they compete for hormone with antibodies used in the assay. These antibodies may cause spuriously high or low results, depending on the assay used. Thyroid hormones are stable at 37° C for 5 days, provided the samples are stored in plastic rather than glass.[40] They are also stable when frozen, even with repeated freezing and thawing. Samples should be stored and shipped in plastic tubes.

238.2.7.2.1

Total T_4 concentration

Total T_4 concentration is an excellent screening test for canine thyroid dysfunction (Figure 238-4). A dog with a TT_4 concentration well within the reference range is euthyroid, unless anti-T_4 antibodies are causing a spurious increase in the TT_4 value. This is uncommon, because anti-T_4 antibodies are detected in less than 2% of samples from dogs with suspected hypothyroidism,[41] and antibody interference most commonly results in TT_4 measurements outside the reference range. Unfortunately, decreased TT_4 concentration is not specific for a diagnosis of hypothyroidism. Decreased TT_4 may be normal for an individual, a result of nonthyroidal illness, or secondary to drug administration. The reference range for TT_4 concentration depends on the laboratory but is usually 1.5 to 3.5 μg/dL. Time of day, age, breed, season, and ambient temperature may influence serum TT_4 concentration. In healthy euthyroid dogs, TT_4 concentration may decrease below the reference range as much as 20% of the time, but there is no predictable diurnal pattern.[42] Serum TT_4 concentrations in neonates are similar to those of young adult dogs; they then increase to more than two to five times the adult concentration by 3 weeks of age. Total T_4 concentrations return to that of the adult dog by 12 weeks of age, then gradually decline with age.[43]

Total T_4 concentrations do not differ significantly between males and females but are higher in small dogs than in medium and large breed dogs.[43] Greyhounds and Scottish deerhounds have lower TT_4 concentrations than other breeds.[44] During diestrus and pregnancy, TT_4 concentration increases owing to changes in thyroid hormone protein binding. Mild increases in TT_4 concentration may also occur in obese dogs.

238.2.7.2.2

Free T_4 concentration

Protein-bound hormone acts as a reservoir to maintain concentrations of free hormone in plasma despite fluctuations in release or metabolism of T_3 and T_4, or in plasma protein concentrations. Thus free hormone concentrations are less affected by changes in protein concentration and binding than are total hormone measurements. Because only free hormone can enter cells and bind to receptors, measurement of fT_4 should give a more accurate representation of thyroid function. In humans, fT_4 concentration often remains normal during nonthyroidal illness, but this does not always occur in dogs. The standard method for measuring fT_4 is equilibrium dialysis. Because this is expensive and time consuming, single-stage solid phase (analog) radioimmunoassays for human fT_4 are sometimes used for measurement of canine fT_4. These assays depend on the dominance of thyroid hormone binding by TBG, concentrations of which are lower in dogs than in humans. Canine fT_4 concentrations measured by analog methods are lower than those measured by equilibrium dialysis and have no diagnostic advantage over measurement of TT_4. A commercial fT_4 assay that uses an equilibrium dialysis step is more accurate than analog methods and is more sensitive and specific for canine hypothyroidism than is measurement of TT_4.[45,46] This assay is also unaffected by anti-T_4 antibodies and is the most accurate single hormone measurement for diagnosis of hypothyroidism.

238.2.7.2.3 Total T_3 concentration

Measurement of TT_3 concentration is less accurate than TT_4 measurement for distinguishing euthyroid from hypothyroid dogs, because TT_3 concentrations fluctuate out of the normal range even more than TT_4 concentrations in euthyroid dogs.[42] Spurious results may occur because of anti-T_3 antibodies.

238.2.7.2.4 Reverse T_3 and free T_3 concentrations

In humans, one mechanism for the euthyroid sick syndrome is decreased 5′-deiodinase activity. This results in a reciprocal relationship between T_3 and rT_3 concentrations. Although this change was documented experimentally in dogs[47], it does not occur predictably in all dogs with nonthyroidal illness. The clinical utility of measurement of rT_3 or fT_3 in dogs has not been demonstrated.

238.2.7.3 Effect of Drugs on Thyroid Hormone Concentrations

Drug administration can change thyroid hormone concentrations in dogs.[48] Glucocorticoids influence peripheral metabolism of thyroid hormones and inhibit TSH secretion. The effect of glucocorticoids is dependent on the dose and specific preparation. In most studies oral administration of glucocorticoids at immunosuppressive doses (1 to 2 mg/kg q12h) resulted in rapid decreases in TT_4, fT_4, and T_3, but little change in serum TSH.[48] Thyroid hormones return to normal within 1 week after stopping treatment if dosing is for 3 weeks or less. Longer treatment may prolong duration of suppression.

Sulfonamides block iodination of thyroglobulin and can cause clinical hypothyroidism in a dose and duration dependent manner. Trimethoprim-sulfadiazine (15 mg/kg q12h) had no effect on thyroid function but caused clinical hypothyroidism at a dose of 24 mg/kg every 12 hours for 40 days.[48] Trimethoprim-sulfamethoxazole at a dose of 30 mg/kg orally every 12 hours decreased TT_4 and TT_3 concentrations, increased TSH, and decreased response to TSH administration within 4 weeks. Effects are reversible within 2 to 4 weeks of discontinuation of therapy. Phenobarbital administration causes decreased TT_4 and fT4 concentrations and mild increases in TSH concentration. Whether dogs treated with phenobarbital have mild clinical signs of hypothyroidism is difficult to assess. Clomipramine results in decreased TT_4 and fT4 concentrations but no change in TSH concentration. Other drugs that may affect thyroid hormone concentrations in dogs include androgens, furosemide, heparin, nonsteroidal anti-inflammatory drugs, propranolol, amiodarone, radiocontrast agents, and iodide.[48]

238.2.7.4 Effect of Systemic Illness on Thyroid Hormone Concentrations

In nonthyroidal illness, thyroid hormone concentrations are often decreased. Changes in hormone binding to serum carrier proteins (e.g., decreased protein concentration, reduced binding affinity, circulating inhibitors of binding), or peripheral hormone distribution and metabolism (e.g., reduced 5′-deiodinase activity), inhibition of TSH secretion, and inhibition of thyroid hormone synthesis may occur. Cytokines such as interleukin-1, interleukin-2, interferon gamma, and tumor necrosis factor alpha decrease TT_4 concentrations.[49] In dogs, TT_4 concentration is more frequently decreased than is TT_3 concentration. The

magnitude of decrease depends on disease severity and is a predictor of mortality.[50] Thyroid hormone supplementation does not improve survival in euthyroid humans with decreased thyroid hormone concentrations. Conditions reported to decrease TT_4 concentrations in dogs include hyperadrenocorticism, diabetic ketoacidosis, hypoadrenocorticism, renal failure, hepatic disease, peripheral neuropathy, generalized megaesophagus, heart failure, critical illness or infection, and surgery or anesthesia.[50–54] In 59 euthyroid dogs with concurrent illness, 20% had low TT_4 concentrations and 17% had low fT_4 concentrations.[51] In 67 critically ill euthyroid animals, 61% had low T_4 concentrations and 56% had low T_3 concentrations.[50] In 42 dogs with hyperadrenocorticism, 38% had low TT_4, 24% had low fT_4, and 39% had low TT_3 concentrations.[52] Dogs with chronic weight loss had decreased TT_4 and TT_3 concentrations regardless of the cause of weight loss.[54]

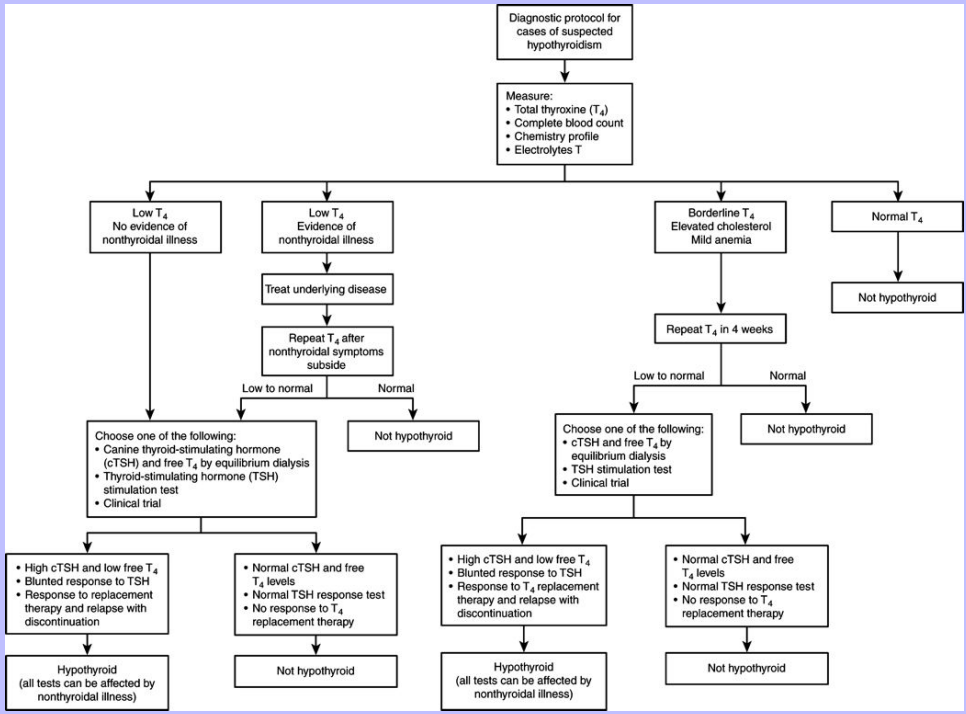
1541

Figure 238-4 Algorithm for diagnosis of hypothyroidism.



238.2.7.5 Basal Thyrotropin (TSH) Concentration

Because of the negative feedback effect of TT_4 on the pituitary gland, measurement of canine TSH concentration should be an accurate indicator of thyroid dysfunction. However, current assays for canine TSH have poor sensitivity for diagnosis of hypothyroidism. From 13% to 38% of hypothyroid dogs have a TSH concentration within the reference range.[45,46,55,56] Possible reasons for a normal TSH concentration in hypothyroid dogs include secondary or tertiary hypothyroidism, fluctuation in TSH concentration, and effect of drugs or concurrent illness. In addition, the TSH assay may not detect all isoforms of circulating

TSH. Although some hypothyroid dogs with normal or low TSH concentrations have secondary or tertiary hypothyroidism, it is unlikely that this accounts for most hypothyroid dogs with normal TSH concentrations. Serum TSH concentrations in hypothyroid dogs fluctuate into the normal range, but there is no predictable pattern.[57] In hypothyroid humans, concurrent illness and drugs can decrease TSH concentration toward or into the high-normal range.

Specificity of TSH alone for diagnosis of hypothyroidism is lower than measurement of fT_4 or TT_4 because TSH concentrations are increased in 7% to 18% of euthyroid dogs. Reasons for increased TSH with a normal TT_4 include early hypothyroidism, effects of drugs and recovery from nonthyroidal illness. TSH concentrations remain within the reference range in most euthyroid dogs with concurrent illness.[58] Specificity of TSH for diagnosis of hypothyroidism in dogs with concurrently low TT_4 or fT_4 approaches 100% (Table 238-1).[45,55]

238.2.7.5.1

TSH response test

The TSH response test is a test of thyroid gland reserve and is the criterion standard for diagnosis of canine hypothyroidism. Clinical use of this test is limited by the availability and expense of medical grade bovine TSH. Life-threatening reactions may occur in some dogs following use of chemical grade TSH. The most widely accepted protocol for the TSH stimulation test is measurement of TT4 followed by intravenous administration of bovine TSH at 0.1 units/kg (maximum 5 units). A second sample for measurement of TT_4 is collected 6 hours later. Other protocols use a fixed dose of 1 to 5 units per dog; however, lower TSH doses result in smaller and less prolonged increases in TT_4 concentration and more borderline responses in pets. Recombinant human TSH may also be used at a dose of 25 to 100 µg IV but is expensive.[59] Reconstituted TSH may be refrigerated for up to 3 weeks or frozen at −20°C for up to 6 months.[60,61]

Table • 238-1 Performance of Various Diagnostic Tests for Hypothyroidism in Dogs*

	SENSITIVITY	SPECIFICITY	ACCURACY
Total T_4	89% to 100%	75% to 82%	85%
Free T_4	80% to 98%	93% to 94%	95%
TSH	63% to 87%	82% to 93%	80% to 84%
TSH/T4†	63% to 67%	98% to 100%	82% to 88%
TSH/free T_4†	74%	98%	86%

* The data are compiled from three published studies of a total of 100 hypothyroid dogs and 164 euthyroid dogs.45,46,56 Not all studies evaluated all diagnostic tests listed.

† A dog was considered to have hypothyroidism only if the T4 or free T4 was low and the TSH was high.

A diagnosis of hypothyroidism is likely if both pre-and post-TSH serum T_4 concentrations are below the reference range (<1.5 µg/dL). A post-TSH T_4 concentration greater than 3 µg/dL indicates euthyroidism.[60–63] Interpretation of intermediate results is more difficult and should take into consideration the clinical signs and severity of concurrent systemic disease. Change in TT_3 before and

after TSH administration is of little diagnostic utility. The TSH response test cannot be used to evaluate thyroid function in dogs receiving T_4, because treatment causes thyroid atrophy. Supplementation must be discontinued 6 to 8 weeks before testing.

238.2.7.5.2

TRH response test

The TRH response test is used in humans to differentiate primary from secondary hypothyroidism. In people with primary hypothyroidism response of TSH to TRH administration is exaggerated, whereas in secondary hypothyroidism there is no response. In contrast, most hypothyroid dogs have a decreased TSH response to TRH compared with euthyroid dogs.[64] The TRH response test is therefore not useful for differentiation of primary and secondary hypothyroidism in dogs.

In dogs, the TRH response test is most commonly used in place of the TSH response test, and change in TT_4 is usually measured. Doses ranging from 0.01 to 0.1 mg/kg of TRH have been evaluated.[63–66] Lower doses cause similar increases in TT4 as do higher doses and are less likely to result in side effects such as salivation, vomiting, urination, defecation, miosis, tachycardia, or tachypnea. A common protocol is administration of 200 μg TRH per dog intravenously with blood collected before and 4 hours after TRH administration.[64] Freshly reconstituted TRH may be frozen at −20°C for at least a week without a loss in potency. Euthyroidism is likely if the post-TRH TT_4 concentration is greater than 2 μg/dL. Euthyroidism is also more likely if there is a relative increase in TSH of greater than 100% at 30 minutes after TRH administration.[64] A diagnosis of hypothyroidism is possible if the post-TRH TT_4 concentration is below the reference range (< 1.5 μg/dL); however, some euthyroid dogs fail to respond to TRH. The TRH response test is therefore less reliable than the TSH response test for diagnosis of canine hypothyroidism.[66]

238.2.7.5.3

Scintigraphy

Few studies evaluate the use of scintigraphy for diagnosis of thyroid dysfunction in the dog. Dogs with normal thyroid function have a median thyroid: salivary (T:S) ratio of approximately 1 at 20 and 60 minutes after injection of ^{99m}Tc-pertechnetate.[67] Decreased thyroid uptake of pertechnetate is reported in hypothyroid dogs, but increased uptake of pertechnetate was documented in a hypothyroid dog with thyroiditis. Further evaluation of scintigraphic findings in canine hypothyroidism is necessary. Scintigraphy can identify the underlying cause in puppies with congenital hypothyroidism. In puppies with thyroid agenesis, minimal uptake of pertechnetate in the area of the thyroid gland is detected, whereas in those with iodination defects, thyroid lobes are large, with normal or increased T:S ratios. Scintigraphy may also help identify central hypothyroidism. Administration of TSH for 3 days does not alter the thyroid image in dogs with primary hypothyroidism but does result in increased thyroid uptake in dogs with central hypothyroidism.[10] Radioactive iodine uptake and perchlorate discharge tests may also be useful in characterization of dogs with congenital hypothyroidism.[12]

238.2.8 Diagnosis of Thyroiditis

238.2.8.1 Antithyroglobulin Antibody

Antithyroglobulin antibodies (ATA) are found in 36% to 50% of hypothyroid dogs.[3–4] A commercially available enzyme linked immunosorbent assay (ELISA) for ATA is a sensitive and specific indicator of thyroiditis, with false-positive results occurring in less than 5% of dogs with other endocrine disorders.[3] Importantly, a positive ATA titer is not diagnostic of abnormal thyroid function because subclinical thyroiditis may be present for long periods of time before progression to hypothyroidism. In addition, vaccination can result in transient increases in ATA titer.[68] It is unknown whether all dogs with ATA ultimately develop hypothyroidism. In 171 euthyroid dogs with ATA followed for 12 months, 4% progressed to overt hypothyroidism, 13% developed some evidence of thyroid dysfunction, and 15% became antibody negative.[8] It is likely that the natural history of thyroiditis varies from breed to breed. Breeds with increased prevalence of antithyroglobulin antibodies include the golden retriever, great Dane, English and Irish setters, Doberman pinscher, Old English sheepdog, dalmatian, basenji, Rhodesian ridgeback, boxer, Maltese, Chesapeake Bay retriever, Cocker spaniel, Shetland sheepdog, Siberian husky, border collie, and Akita.[8] Measurement of ATA has been advocated for screening breeding stock, with the aim of ultimately eliminating heritable forms of thyroiditis. Whether this is an effective approach has yet to be demonstrated.

238.2.8.2 Anti-T_3 and-T_4 Antibodies

Antibodies directed against T_3 and T_4 (THAA) also occur in canine thyroiditis, although they are less prevalent than ATA. Because T_3 and T_4 alone are small molecules, these antibodies probably develop against T_3-and T_4-containing epitopes of thyroglobulin. Anti-T_3 antibodies are found in only 5.7% of samples from dogs with clinical signs consistent with hypothyroidism but in 34% of confirmed hypothyroid dogs. Anti-T_4 antibodies are found in 1.7% of samples from dogs with clinical signs consistent with hypothyroidism but are found in 15% of confirmed hypothyroid dogs.[8,41] Because dogs with thyroiditis may still have adequate thyroid reserve, THAA are not diagnostic of hypothyroidism. Prevalence of THAA is highest in younger dogs (2 to 4 years), large-breed dogs, and females. Dog breeds with a high prevalence of THAA include pointers, English and Irish setters, Skye terriers, Old English sheepdogs, boxers, and Maltese terriers.[41]

238.2.8.3 Thyroid Biopsy

Lymphocytic thyroiditis is readily identified by histopathology, but it is more difficult to determine thyroid function. Thyroid biopsy is rarely indicated for clinical diagnosis of thyroid dysfunction.

238.2.9 Treatment and Therapeutic Monitoring

238.2.9.1 Hypothyroidism

The initial treatment of choice regardless of the underlying cause of the disease, is synthetic sodium *l*-thyroxine (T_4). Treatment with T_4 preserves normal regulation of T_4 to T_3 conversion, which allows normal physiologic regulation of tissue T_3 concentrations and therefore should decrease the likelihood of iatrogenic hyperthyroidism. Treatment with synthetic T_3 is not recommended because of an increased risk of iatrogenic hyperthyroidism. In addition, T_3 has a shorter half-life and requires administration three times daily. Treatment with T_3 may be indicated if there is inadequate gastrointestinal absorption of T_4. Gastrointestinal absorption of ingested T_3 approaches 100%, whereas oral bioavailability of T_4 is lower, at 10% to 50%. Treatment with T_3 was previously advocated in suspected hypothyroid dogs with a normal T_4 but a low T_3; however, this is no longer recommended. This scenario was thought to be due to a T_4 to T_3 conversion defect, but such a defect has not been documented in dogs. Rather, this hormone profile likely represents sick euthyroid syndrome, presence of anti-T_3 antibodies, or normal daily fluctuations in plasma T_3 concentration.

The use of desiccated thyroid extract, thyroglobulin, or “natural” thyroid preparations is not recommended because the bioavailability and T_4:T_3 ratio of these compounds is variable, making consistent dosing difficult. In humans, substitution of T_3 for some of the T_4 dose is associated with an improved psychologic state in some studies, possibly because tissues vary in their ability to convert T_4 to T_3.[69] Commercially available combination T_4/T_3 products contain a T_4:T_3 ratio of 4:1, and may predispose to iatrogenic hyperthyroidism because the normal ratio of T_4:T_3 secreted by the thyroid gland is approximately 20:1.

Optimum dose and frequency of supplementation varies among dogs because of variability in T_4 absorption and serum half-life.[70] A dose of 0.02 mg/kg q24h normalizes TSH concentration in most dogs; higher doses (0.04 mg/kg q12h) are required to consistently normalize T_3 concentration,[71–72] but there is little evidence that normalization of T_3 is necessary for a good clinical response. Treatment should be initiated at a dose of 0.02 mg/kg PO q12h and the dose adjusted based on the measured serum T_4 concentration (Figure 238-5). Twice daily treatment with T_4 is initially recommended to improve the likelihood of response to treatment. If clinical signs resolve and T_4 concentrations are within the therapeutic range, the frequency of T_4 administration may be decreased to once daily. It is advisable to use a brand-name product for initial treatment because studies in people have shown large variability in the bioavailability of generic products. Name brand canine and human products appear to have similar bioavailability.[72,73]

Adequacy of therapy should be confirmed by therapeutic monitoring 4 to 8 weeks after beginning supplementation. Serum T_4 concentration should be within the reference range immediately prior to administration of a dose, and at the high end or slightly above the reference range 4 to 6 hours after administration of a dose. This is a clinically effective approach but it may result in over-supplementation in some dogs. Current assays for TSH are not sensitive enough to distinguish a normal from a low TSH concentration and thus cannot distinguish between those dogs that are adequately supplemented and those that are over-supplemented. Dogs are believed to be relatively resistant to development of iatrogenic

hyperthyroidism because of the short half-life of T_4 in this species, however the risk of long-term over-supplementation of thyroid hormone in dogs has not been investigated. Serum T_4 concentrations should be measured at 6-to 8-week intervals during the first 6 to 8 months of treatment, because metabolism of T_4 changes as the metabolic rate normalizes. Frequency of serum T_4 measurement may then be decreased to once or twice a year. If the brand of supplement is changed, serum T_4 concentration should be measured 4 to 8 weeks after the change.

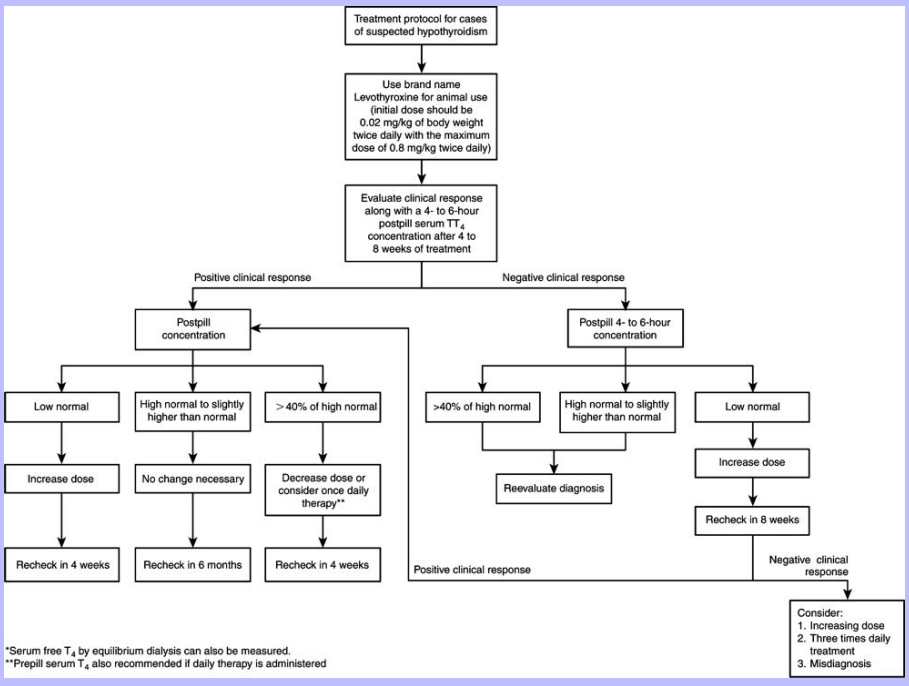
The majority of hypothyroid dogs demonstrate good control of their disease at a dose of 0.02 mg/kg T_4 administered orally once daily.[74] However, therapy should be individualized based on clinical response, therapeutic monitoring, and presence or absence of concurrent illness. Improvement in activity should occur within the first 1 to 2 weeks of treatment; weight loss should be evident within 8 weeks.[14] Achievement of a normal hair coat may take several months and the coat may initially appear worse as telogen hairs are shed.[75] Improvement in myocardial function is usually evident within 8 weeks, but may be delayed for as long as 12 months. Neurologic deficits improve rapidly after treatment but complete resolution may take 8 to 12 weeks.[22]

Inadequate supplementation with thyroid hormone results in an incomplete clinical response. It may be difficult to establish what is normal for some dogs, because subtle clinical signs of hypothyroidism may have been present for so long that the owners do not know what activity level is normal for their dog. This is one reason therapeutic monitoring is important. Some hypothyroid humans do not have complete resolution of clinical signs unless treated with a small amount of T_3 in addition to T_4. Whether this is also the case in some dogs is unknown.

1542

1544

Figure 238-5 Algorithm for treatment of hypothyroidism.



In myxedema coma, T_4 should be administered initially intravenously (5 μg/kg) because of poor gastrointestinal absorption due to hypomotility. Other supportive care including appropriate fluid therapy, passive rewarming, and ventilatory support may also be necessary.

238.2.9.2 Concurrent Nonthyroidal Illness

238.2.9.2.1 Cardiomyopathy

In hypothyroid dogs with cardiac disorders, thyroid hormone supplementation increases myocardial oxygen demand and may cause cardiac decompensation. Initial doses of thyroid hormone replacement should be 25% to 50% of the usual starting dose. The dose may then be increased incrementally based on the results of therapeutic monitoring and reevaluation of cardiac function. Because euthyroid dogs with cardiac disease may have decreased thyroid hormone concentrations, it is important to adequately document hypothyroidism to avoid inappropriate treatment.

238.2.9.2.2 Hypoadrenocorticism

Replacement of mineralocorticoid and glucocorticoid deficiency should be initiated before treatment with T_4, because the increased basal metabolic rate may exacerbate electrolyte disturbances.

238.2.10 Treatment Failure

An incorrect diagnosis of hypothyroidism is the most common reason for treatment failure. Diseases such as hyperadrenocorticism, atopy, and flea hypersensitivity may have clinical signs similar to those of hypothyroidism and often are associated with decreased thyroid hormone concentrations (sick euthyroid syndrome). Other causes include insufficient absorption from the gastrointestinal tract or poor owner compliance. If poor gastrointestinal absorption is suspected, T_3 may be substituted for T_4 (4 to 6 μg/kg q8h).

238.2.11 Prognosis

Prognosis for return to normal function following treatment is excellent in most adult hypothyroid dogs. Prognosis in myxedema coma is dependent on early recognition. Resolution of clinical signs in puppies with congenital hypothyroidism is dependent on the age at which treatment is initiated.

238.3 FELINE HYPOTHYROIDISM

Naturally occurring hypothyroidism is rare in cats. The most common cause of low serum TT_4 in cats is nonthyroidal illness. Iatrogenic hypothyroidism occasionally occurs following treatment for hyperthyroidism. Clinical signs of hypothyroidism in cats are similar to those reported for dogs. Causes of spontaneous feline hypothyroidism include congenital hypothyroidism in domestic shorthair cats and Abyssinian cats[76–78] and lymphocytic thyroiditis reported in a 5-year-old cat and in young kittens.[79,80]

Diagnosis of feline hypothyroidism is confirmed by physical examination, history, measurement of serum TT_4 concentration, and results of TSH or TRH stimulation tests. For a TSH stimulation test, TSH is administered at 1

IU/cat intravenously or 2.5 to 5 IU/cat intramuscularly.[81] Blood samples are collected before injection and 4 to 7 hours after intravenous injection or 8 to 12 hours after intramuscular injection. Serum TT_4 concentration should double after TSH administration. The dose of TRH is 0.1 mg/kg given intravenously, with blood collected before and 4 to 6 hours after injection. Serum TT_4 concentration should increase by greater than 50% after TRH administration. Immediate transient side effects following TRH administration include salivation, vomiting, tachypnea, and defecation. A commercial assay for canine TSH has been validated for feline use. A high TSH measured using this assay in conjunction with a low T_4 in the presence of appropriate clinical signs supports a diagnosis of hypothyroidism.

Hypothyroid cats may be treated with T_4 at a dosage of 0.05 to 0.1 mg/cat given orally once daily. Therapeutic monitoring and dosage adjustments should be performed as recommended for dogs.

239 CHAPTER • 239 Hyperthyroidism

Carmel T. Mooney

239.1 FELINE HYPERTHYROIDISM

Hyperthyroidism (thyrotoxicosis) is a multisystemic disorder arising from the excess production of the active thyroid hormones (triiodothyronine [T_3] and/or thyroxine [T_4]) from an abnormally functioning thyroid gland.[1] In cats, this condition was first definitively diagnosed in the late 1970s. Its prevalence has increased significantly such that it is now recognized not only as the most common endocrine disease of the cat but also as one of the more frequently diagnosed disorders in small animal practice.

239.1.1 Etiopathogenesis

Functional adenomatous hyperplasia (or less frequently adenoma) of one (approximately 30% of cases) or, more commonly, both (70% of cases) thyroid lobes is the most common abnormality associated with hyperthyroidism in cats.[1–6] On histologic examination, the normal thyroid follicular architecture is replaced by one or more, well-discernible foci of hyperplastic tissue that can form nodules ranging in size from less than 1 mm to greater than 3 mm, with wide variation in follicular size and architecture both within and between individual nodules.[4] Normal but compressed thyroid tissue is often found surrounding abnormal follicles, but occasionally zones of smooth transition between normal and hyperplastic tissue are present. Thyroid carcinoma, by contrast, is rare, accounting for less than 2% of hyperthyroid cases.[1,7]

Prior to 1979, when hyperthyroidism was first definitively diagnosed, there were a few anecdotal reports of thyroid abnormalities in cats but rarely with clinical signs.[7] However, the frequency with which hyperthyroidism is diagnosed has since increased dramatically.[8] Retrospective necropsy studies reveal few cats with thyroid abnormalities prior to 1979,[7] whereas clinical studies demonstrate a significant increase in cases since that time. In the Animal Medical Center, New York, approximately three hyperthyroid cases per month were seen in 1983; this increased to 22 cases per month in 1993, despite a similar feline caseload.[9] Increased awareness and easier availability of thyroid hormone assays alone is unlikely to account for the dramatic increased frequency of diagnosing this disease, and it has been suggested that it is truly a new disease of cats. However, it remains unclear whether this disorder is simply diagnosed more frequently because of both a general growth in the pet cat population and an overall increase in the longevity of the cat.[9]

Although the disorder and its pathologic lesions have by now been well described, the cause remains obscure. Histologically the disease most closely resembles human toxic nodular goiter, although the fact that bilateral involvement is more common (despite no clear anatomic link between the two thyroid lobes) is reminiscent of human Graves' disease. Graves' disease is an autoimmune disorder in which circulating antibodies (thyroid-stimulating immunoglobulins [TSIs]) bind to thyrotropin (thyroid-stimulating hormone [TSH]) receptors and mimic TSH. Initial studies in hyperthyroid cats suggested that autoantibodies (thyroid microsomal and antinuclear) were common and could be involved in the pathogenesis of the condition.[10] However, four separate studies, using three different techniques, including transfected cells expressing the TSH receptor gene, have failed to identify TSIs in hyperthyroid cats.[11–14] Increased titers of

growth-stimulating immunoglobulins have been demonstrated in hyperthyroid cats but their role in the pathogenesis of the condition is unclear.[13]

As in human toxic nodular goiter, adenomatous thyroid tissue from hyperthyroid cats retains its histologic appearance and continues to grow and function when transplanted onto nude mice.[4] Thyroid cells from affected cats, cultured in TSH-free media, also continue to grow and hyperfunction.[15] Somatic mutations of the TSH receptor gene are an important cause of toxic adenoma in humans. However, one research group investigating the possibility of such a cause in cats did not find any corresponding mutations between codons 480 and 640 of the feline TSH receptor gene—the area corresponding to the majority of human disease.[16] Extending such a study to include codons 66 to 530, allowing inclusion of the transmembrane and most of the extracellular part of the TSH receptor, also found no mutations, suggesting that the pathogenesis of hyperthyroidism in cats is unlikely to involve mutations in this gene.[17] After TSH binds to its receptor, signal transduction is cyclic adenosine monophosphate (cAMP)-dependent via a G protein–mediated pathway. Decreased expression of a G protein (specifically G_{i2}) that is normally involved in inhibition of a wide range of G protein–dependent intracellular signaling processes (amongst them the signal to secrete thyroid hormones) has been demonstrated in hyperthyroid cats.[18,19] A more recent study has suggested that mutations in the $G_{s\alpha}$ gene found in some hyperthyroid cats may play a role in the development of adenomatous hyperplasia.[17]

Thyroid tissue from hyperthyroid cats has also been examined immunohistochemically to identify expression of the oncogenes c-ras, bc12, and the tumor suppressor gene p53. Overexpression of the product of c-ras has been demonstrated but without detectable staining for either bc12 or p53. Gain-of-function mutations in this oncogene may therefore play a role in the etiopathogenesis of the feline disease.[20]

Several epidemiologic studies have attempted to uncover risk factors that may be implicated in the pathogenesis of the disease. Two separate studies have reported that two genetically related breeds, the Siamese and Himalayan, are at decreased risk of developing hyperthyroidism.[8,21] Cats fed almost entirely canned food and those using cat litter have an increased risk of developing hyperthyroidism.[8,21] In addition, cats that prefer to eat certain flavors of canned cat food (fish or liver and giblet flavor) have a significantly increased risk of developing hyperthyroidism.[22] Because of this dietary association, iodine has been implicated in the cause or progression of the disease. The iodine content of cat food is extremely variable and often up to 10 times the recommended level.[23,24] It has been postulated that wide swings in daily iodine intake may somehow contribute to the development of thyroid disease. Although serum free T_4 concentrations may be acutely affected by varying iodine intake, more prolonged ingestion has no apparent statistical effect.[25,26] Selenium status could also potentially modify thyroid function. One study found no difference in selenium status in cats from different geographic regions with high and low prevalence of hyperthyroidism but did find that cats had higher circulating selenium concentrations than other species (possibly as a result of increased intake) that may play a role in the pathogenesis of the condition.[27] Many other goitrogenic compounds exist (e.g., phthalates) that can contribute to the development of adenomatous lesions in exposed cats. These may be of particular importance because most are metabolized by glucuronidation, a metabolic pathway particularly slow in the cat. A recent study has shown that the potentially goitrogenic soy isoflavones, genistein, and daidzein, are common constituents of commercially available cat foods and may be present in concentrations sufficient to result in some biologic effect.[28]

239.1.2 Clinical Features

Hyperthyroidism is a disease of middle-aged to older cats, with an average age of onset of 12 to 13 years.[2,6,9,29] Although the reported age range is 4 to over 20 years, less than 5% of cats are younger than 10 years of age at the time of diagnosis.[1] There has been a recent report of hyperthyroidism in an 8-month-old kitten, but thyroid histologic changes were unlike those found in adult cats and are likely to represent a separate disease entity.[30] No sex predisposition exists, and despite the decreased risk of developing hyperthyroidism associated with certain breeds, most large case studies have failed to identify a breed predilection.[2,6,9,29]

Thyroid hormones are responsible for a wide variety of actions including the regulation of heat production and carbohydrate, protein, and lipid metabolism. They also interact with the nervous system, increasing overall sympathetic drive. Consequently, almost any organ can be involved, and a variety of clinical signs are possible in hyperthyroid animals. Table 239-1 lists the most common clinical signs recorded in cats from previous and more recent studies. Both the number and severity of the clinical signs vary in individual cats, depending on the duration of the condition, the ability of the cat to cope with the demands of thyroid hormone excess, and 1545 1546 the presence or absence of concomitant abnormalities in other organ systems.[6] The disease is insidiously progressive, and owners may consider the signs, when mild, as part of the generalized aging process. Therefore months may elapse before veterinary attention is sought. Cats are less symptomatic today compared with 10 or 15 years ago, presumably because of increased awareness and earlier diagnosis. It is now not unusual for hyperthyroidism to be confirmed before owners fully realize their cats are ill.[9,31] Although the combination of certain clinical signs (weight loss despite a normal or increased appetite, hyperactivity, intermittent gastrointestinal (GI) signs, palpable goiter, tachycardia, and cardiac murmur) is highly suggestive of hyperthyroidism, the presence or absence of any one sign cannot confirm or exclude the disorder. Clinical signs suggestive of dysfunction of only one organ system may predominate in some cats; as a consequence, hyperthyroidism is considered an important differential for many presenting features in older cats.

239.1.2.1 General Features

Weight loss is the most common feature of hyperthyroidism occurring in over 80% of cats, resulting in overt cachexia in severe cases.[2,6,9,29] This reflects the overall increase in metabolic rate that may be accompanied by a mild elevation in body temperature or heat intolerance.

Hyperthyroidism is associated with hyperactivity in many affected cats. This may be more noticeable during a physical examination than to the owners, because the cats are often restless, difficult to examine, and may become aggressive, when restrained. Hyperthyroid cats are often described as having an anxious or frantic facial expression and have an impaired tolerance to stress.[2,29,32] In severe cases, stressful events, such as blood sampling, can result in collapse, cardiac arrhythmias, and dyspnea; care should be taken to handle hyperthyroid cats appropriately. Some hyperthyroid cats wander aimlessly, pace, and circle (presumably reflecting a state of confusion, anxiety, and nervousness).[32] Sleep may be abbreviated, and cats may be awakened easily.[32] Focal or generalized seizures characteristic of epilepsy have developed in a few rare cases, with lessening or resolution of the seizures after treatment of the hyperthyroidism.[32]

Table • 239-1 Clinical Findings in 131 Cats (1983 Survey) Compared with 202 Cats (1993 Survey)

FEATURE	NUMBER (%) OF CATS 1983 SURVEY	NUMBER (%) OF CATS 1993 SURVEY
Weight loss	128 (98%)	177 (87%)
Polyphagia*	106 (81%)	99 (49%)
Hyperactivity*	99 (76%)	63 (31%)
Tachycardia*	87 (66%)	85 (42%)
Polyuria/polydipsia*	78 (60%)	73 (36%)
Vomiting	72 (55%)	89 (44%)
Cardiac murmur	70 (53%)	109 (54%)
Diarrhea*	43 (33%)	30 (15%)
Increased fecal volume*	41 (31%)	17 (8%)
Anorexia*	34 (26%)	14 (7%)
Panting*	33 (25%)	19 (9%)
Muscle weakness*	33 (25%)	24 (12%)
Congestive heart failure (CHF)*	16 (12%)	4 (2%)
Increased nail growth	15 (12%)	13 (6%)
Dyspnea	14 (11%)	20 (10%)
Alopecia	9 (7%)	6 (3%)
Ventroflexion of neck	4 (3%)	2 (1%)
Palpable goiter	118 (90%)	167 (83%)

Data from Peterson ME et al: Feline hyperthyroidism: pretreatment clinical and laboratory evaluation of 131 cases. J Am Vet Med Assoc 183:103, 1983; Broussard JD et al: Changes in clinical and laboratory findings in cats with hyperthyroidism from 1983 to 1993. J Am Vet Med Assoc 206:302, 1995.

* There was a significant decrease in the prevalence of the finding between the surveys.

Muscle weakness and muscle atrophy with fatigability are occasionally described. Owners may describe a decreased ability to jump or fatigue after short bursts of physical activity.[1,2,32] The pathophysiology of muscle weakness is unclear but presumably is related to the thyrotoxicosis-associated weight loss. Severe muscle weakness (exhibited by ventroflexion of the neck) is rarely described and may result from hypokalemia recently reported in hyperthyroid cats.[6,33]

In previous case series, hair and coat changes were common. Shorthaired cats frequently had an unkempt and even matted coat, presumably due to undergrooming, whereas some longhaired cats had alopecia, presumably due to excess grooming.[6,29] Excessive nail growth with increased fragility has also been described.[6,29] These signs are less commonly noted today.

Polyuria and polydipsia reportedly occur in less than 50% of hyperthyroid cats but can be marked in individual cats.[9] Various mechanisms may be responsible, including concurrent primary renal disease (not unexpected in a group of aged cats), increased renal blood flow decreasing medullary solute concentration gradient, electrolyte abnormalities, and primary polydipsia because of a hypothalamic disturbance induced by thyroid hormone excess.[1] Hyperthyroidism could contribute to the development of renal disease in cats. The systemic hypertension accompanying hyperthyroidism could be transmitted to glomeruli, and in the absence of autoregulation, intraglomerular hypertension and glomerular hyperfiltration potentially results.[34] These factors contribute to glomerular sclerosis and progression of renal failure in cats. On the other hand,

hyperthyroidism may prove beneficial in maintaining sustainable renal function in cats with pre-existing renal disease. Overt signs of renal dysfunction may be unmasked upon reversal of the hyperthyroid state, and it is this effect that appears to be of greatest concern when considering treatment of affected cats (see Effect of Treatment on Renal Function).

239.1.2.2 Gastrointestinal Features

While some hyperthyroid cats have no discernible change in appetite, approximately 50% are described as polyphagic.[9] Despite the increased appetite, caloric intake is rarely adequate to compensate for increased energy expenditure, and weight loss generally ensues. Up to 20% of hyperthyroid cats exhibit short periods of anorexia that alternate with longer periods of normal or increased appetite, although the reasons for this are unclear.[6] Cats with apathetic hyperthyroidism usually exhibit partial to complete anorexia (see Apathetic Hyperthyroidism).

Intermittent GI signs of vomiting and, less commonly, diarrhea (increased frequency or volume or steatorrhea) are frequently observed in hyperthyroid cats.[1,2,6,9,29] Rapid overeating may contribute to vomiting, particularly in multicat households; however, direct stimulation of the chemoreceptor trigger zone is also possible.[1,2] Intestinal hypermotility, excess fat intake, and a reversible reduction in pancreatic exocrine function all contribute to the diarrhea associated with hyperthyroidism in humans.[6] Many of these mechanisms have not yet been fully evaluated in cats. However, two separate studies evaluating 10 and 13 hyperthyroid cats each have reported an accelerated orocecal transit time compared with healthy cats and compared with hyperthyroid cats after successful treatment, respectively.[35,36]

1546

1547

239.1.2.3 Cardiovascular Features

Cardiovascular signs are common in hyperthyroidism and are frequently the most significant findings on physical examination (alerting the clinician to the possibility of hyperthyroidism). They include tachycardia, systolic murmurs, a prominent apex beat, and less commonly arrhythmias.[6,29] Systolic murmurs appear to be more commonly recognized than tachycardia in more recent reports.[9] Congestive heart failure (CHF) appears to be uncommon; when it arises it may be associated with a gallop rhythm, coughing, dyspnea, muffled heart sounds, and ascites.[6,9] Hyperthyroidism is usually associated with a form of hypertrophic cardiomyopathy that can result in cardiac failure in the absence of any underlying myocardial abnormalities.[37] Less commonly, a dilated form of cardiomyopathy with severe signs of CHF has been described.[38] Cats with CHF require treatment for both their hyperthyroidism and cardiac failure, using those drugs recommended for the specific form of cardiomyopathy present. While often reversible, cardiomyopathy persists or worsens after treatment in some cats, suggesting a pre-existing cardiac defect or thyroid hormone–induced irreversible structural damage.[39] The exact mechanism for the cardiac abnormalities is unclear but appears to involve a combination of direct action of excess thyroid hormones on the heart, interactions between thyroid hormones and the sympathetic nervous system, and cardiac changes that compensate for altered peripheral tissue function.[2,37]

An early study suggested that mild to moderate hypertension that is reversible after successful induction of euthyroidism is relatively common in hyperthyroid cats.[40] Hypertension in cats has been associated with a variety of ocular abnormalities including retinal detachment, hemorrhage, edema, and degeneration with

resultant blindness.[41] However, in most studies of hyperthyroid cats, obvious ocular signs such as blindness are not reported.[42,29] In addition, fundoscopic examination in hyperthyroid cats rarely reveals retinal lesions even in the presence of hypertension.[41–43] A more recent study has suggested that hyperthyroidism, although causing mild increases in systolic blood pressure, is not often a cause of severe hypertension unless accompanied by renal failure.[44]

239.1.2.4 Respiratory Features

Respiratory abnormalities, chiefly tachypnea, panting, and dyspnea have been reported in hyperthyroid cats, although their prevalence, like other clinical signs, have decreased in recent years.[2,6,9,29] Obviously, these signs occur in cats with CHF. However, they may also be seen in cats without overt cardiac disease and in such cases are often precipitated by stressful events such as veterinary intervention. Proposed explanations include varying combinations of respiratory muscle weakness, increased ventilatory drive to breathing, increased airway resistance, diminished lung compliance and even, albeit rarely, tracheal compression due to an enlarged thyroid gland.[29]

239.1.2.5 Apathetic Hyperthyroidism

Apathetic (occasionally called *masked*) hyperthyroidism is an unusual form of thyrotoxicosis that is seen in approximately 10% of cats.[6,29] In such cases, hyperactivity is replaced by depression and polyphagia by anorexia; weight loss continues unabated. Affected animals can be extremely ill. In human medicine, the term *apathetic hyperthyroidism* is usually restricted to those patients with signs (particularly atrial fibrillation and CHF) induced by excess thyroid hormones and does not include those with concurrent disease.[29] In cats this distinction is not always made. Therefore although many cats are ill as a result of CHF, a significant proportion have concurrent illnesses such as renal failure or neoplasia that account for the majority of their clinical signs. In cats with apathetic signs, a thorough investigation for CHF and other illnesses is indicated because results may alter the therapeutic protocol and eventual prognosis.

239.1.2.6 Palpable Goiter

In healthy cats the thyroid gland is divided into two separate lobes positioned just below the cricoid cartilage. Each lobe extends ventrally over the first five or six tracheal rings and are not normally palpable. Enlargement of one or more thyroid lobes is detectable by palpation in over 80% of cases.[9] With progression of the disease and greater clinician experience, goiter may be detectable in over 95% of cases.[29] Thyroid lobes are loosely anchored to surrounding tissues and as they enlarge tend to migrate ventrally toward the thoracic inlet, occasionally entering the anterior mediastinum. Ectopic thyroid tissue, located anywhere from the base of the tongue to the base of the heart, can also be involved.[45]

Occasionally goiter is visible, but in most cases palpation is required. To palpate for goiter the cat should be restrained by holding its front legs in a sitting position. With the neck gently extended, the thumb and forefingers are placed on either side of the trachea and swept carefully downwards from the larynx to the manubrium. The fingertips should remain within the jugular furrows, but it is important to be gentle and to avoid hyperextension of the neck or the thyroid lobes can become embedded into muscle or deviated retrotracheally. Goiter is usually felt as a mobile subcutaneous nodule or “blip” that slides or slips under the fingertips.[1] When palpation is difficult, clipping the ventrocervical area and moistening the skin with

alcohol may help in the visualization of small mobile nodules. More recently a semiquantitative thyroid palpation technique has been described with the clinician positioned behind the cat and the head raised and turned alternatively to the right or left, depending on which side is being assessed.[46] The degree of enlargement is assigned a score between 1 and 6, linked to the severity of hyperthyroidism. Although considered sensitive, such a technique is highly subjective.

The presence of a cervical mass is not always synonymous with hyperthyroidism. Masses can be associated with lymph node enlargement or parathyroid hyperplasia and neoplasia. In addition, goiter may develop in cats without overt hyperthyroidism, although undoubtedly T_4 secretion increases in many of these individuals with time, necessitating careful and regular re-examinations.[47]

239.1.3 Diagnostic Procedures

A variety of procedures have been recommended for evaluating cats suspected of having hyperthyroidism. The results of screening laboratory tests, diagnostic imaging, and electrocardiography may provide supportive evidence of hyperthyroidism or detail extent of cardiac involvement. Screening laboratory tests are also useful in eliminating other diseases with similar clinical signs or in depicting concurrent disorders potentially masked by hyperthyroidism that may be important in treatment decisions and ultimate prognosis. Specific thyroid function tests are necessary for confirmation of the disorder.

239.1.3.1 Echocardiography and Radiology

Evidence exists of mild to severe cardiac enlargement on thoracic radiography in over 50% of hyperthyroid cats.[31] This is accompanied by evidence of pleural effusion and pulmonary edema in cats with CHF.[6,31] The most common echocardiographic abnormalities include hypertrophy of the left ventricular caudal wall (approximately 70% of cats), left atrial and ventricular dilation (70% and 45% of cats, respectively), and hypertrophy of the interventricular septum (40% of cases).[39] Myocardial hypercontractility, as evidenced by increased shortening fraction and velocity of circumferential fiber shortening, is often found.[39] These abnormalities usually resolve or improve once hyperthyroidism has been effectively treated.[39] Occasionally, hyperthyroidism is associated with a dilated form of cardiomyopathy with echocardiographic evidence of reduced myocardial contractility and marked ventricular dilatation.[38] Thoracic radiographs are necessary in cats suspected of having cardiac failure.

1547 1548

239.1.3.2 Electrocardiography

Sinus tachycardia (approximately 60% of cases) and increased R-wave amplitude in lead II (approximately 30% to 50% of cats) were originally the most frequent abnormalities recorded on electrocardiographic examination of hyperthyroid cats.[2,6,48] Other recorded abnormalities included atrial and ventricular arrhythmias, prolonged QRS duration, shortened Q-T interval, intraventricular conduction disturbances, and ventricular pre-excitation.[2,6,48] A more recent study reported a reduced prevalence of tachyarrhythmias, increased R-wave amplitude in lead II, atrial and ventricular arrhythmias, and conduction disturbances, but an increased prevalence of right bundle branch block.[31] The reason for the latter is unclear.

239.1.3.3 Screening Laboratory Tests

In early reports of hyperthyroidism, mild to moderate erythrocytosis and macrocytosis were common.[2,9] In one study of 131 hyperthyroid cats, an increased packed cell volume (PCV), mean corpuscular volume (MCV), red blood cell (RBC) count, and hemoglobin concentration were reported in 47%, 44%, 21%, and 17% of cats, respectively; the prevalence of such changes remained as high in a study undertaken 10 years later.[6,9] Such changes are thought to reflect increased erythropoietin production resulting from increased oxygen consumption or direct thyroid hormone–mediated beta-adrenergic stimulation of erythroid marrow. Erythropoietin excess is also a potential factor in promoting the release of macrocytes into the circulation. However, in a similar study of hyperthyroid cats from the United Kingdom, there were minimal changes in red cell parameters and macrocytes were rare.[29] Although it is difficult to explain the differences between the studies, it is worth stressing that none of the previously mentioned abnormalities, if observed, is clinically important. Anemia appears to be rare.[6,29] When it occurs it is usually associated with severe hyperthyroidism and may result from bone marrow exhaustion, iron, or other micronutrient deficiency.[29] Despite the lack of overt anemia, a significantly higher prevalence of Heinz body formation has been reported in cats with hyperthyroidism compared with healthy cats, although with fewer and smaller Heinz bodies compared with other diseases.[49] Hyperthyroid cats also appear to have higher mean platelet size than healthy cats, but the significance of this remains unclear.[50]

Changes in white blood cell (WBC) parameters are not unusual in hyperthyroidism but are relatively nonspecific. The most frequent changes include leukocytosis, mature neutrophilia, lymphopenia, and eosinopenia, presumably reflecting a stress response.[2,6,9,29] However, eosinophilia and lymphocytosis have also been described and potentially result from a relative decrease in available cortisol because of excess circulating thyroid hormone concentrations.[29]

The most striking biochemical abnormalities observed in hyperthyroid cats are increases in liver enzyme activities. These include alanine aminotransferase (ALT), alkaline phosphatase (ALKP), lactate dehydrogenase (LDH), and aspartate aminotransferase (AST). In more recent and previous reports, at least one of these enzymes is abnormally increased in over 90% of hyperthyroid cats.[2,6,9,29] The elevations in these enzymes can be dramatic. However, at least in one study serum ALKP and total T_4 concentrations were significantly correlated, and concentrations of ALT and ALKP declined to within reference range with successful induction of euthyroidism.[51,52] As a consequence, the degree of elevation is subtle, if present at all, in early or mild cases of hyperthyroidism. If marked elevation in liver enzyme activities are seen with only mildly abnormal serum thyroid hormone concentrations, concurrent hepatic disease should be suspected and investigated.

Despite the marked increases in hepatic enzyme activities in some hyperthyroid cats, histological examination of hyperthyroid cat livers has revealed only modest and nonspecific change. These include increased pigment within hepatocytes, aggregates of mixed inflammatory cells in the portal regions, and focal areas of fatty degeneration.[2] In more severe cases, centrilobular fatty infiltration may occur together with patchy portal fibrosis, lymphocytic infiltration, and proliferation of bile ducts.[2,6] Suggested explanations for such abnormalities have included malnutrition, CHF, infections, hepatic anoxia, and direct toxic effects of thyroid hormones on the liver. However, several recent reports have examined the possibility of other sources of these enzymes and have shown that both liver and bone contribute to

increased ALKP activity in hyperthyroid cats.[51,53,54] The bone isoenzyme contributes approximately 20% to 30% of total ALKP activity; although frequently increased in hyperthyroid cats, a poor correlation is seen with total T_4 concentrations.[51,54]

Hyperphosphatemia, in the absence of azotemia, was originally reported in approximately 20% of cases, and this has more recently been reported in a higher percentage (36% to 43%) of hyperthyroid cats particularly when compared with an age-matched control group.[54,55] This, together with the increase in the bone isoenzyme of ALKP, is suggestive of altered bone metabolism. Circulating osteocalcin concentration, used as a measure of osteoblastic activity and bone remodeling, although variable, has been shown to be increased in hyperthyroid cats.[54] In human thyrotoxic patients, an increased risk of osteoporosis exists because of a direct effect of thyroid hormone on bone. The net bone loss leads to the release of calcium and a tendency toward hypercalcemia, hyperphosphatemia, hypoparathyroidism, and reduced concentrations of activated vitamin D.[6,55] Early reports suggested that despite hyperphosphatemia, circulating calcium concentration was largely unaffected by hyperthyroidism in cats.[6] However, only total calcium was measured. In two separate studies it has been shown that up to half of hyperthyroid cats have serum ionized calcium concentrations below the reference range.[54,55] In addition, hyperparathyroidism appears to be common and has been demonstrated in over 70% of hyperthyroid cats with maximum parathormone (PTH) values approaching 19 times the upper limit of the reference range.[55] Preliminary results suggest that circulating 1,25 Vitamin D concentrations are not suppressed in cats as in humans.[55] The cause of hyperparathyroidism, hyperphosphatemia, and ionized hypocalcaemia remain unclear and warrant further study. In addition, its clinical consequences are unknown, although the increased secretion of PTH necessary to maintain ionized calcium at the low end or below the reference range might contribute to the tendency of some cats to develop hypocalcemia after surgical thyroidectomy.

In early reports of hyperthyroidism, mild to moderate azotemia appeared to be common, occurring in 25% to 70% of cats.[2,6,29] Current figures suggest that just over 20% of hyperthyroid cats are azotemic.[9] Although such prevalence is not unexpected in a group of aged cats, the increase could be exacerbated by the increased protein catabolism, hypertension, and the possible prerenal uremia of thyrotoxicosis.[2,34] In hyperthyroid cats without azotemia, serum creatinine concentration is significantly lower compared with age-matched healthy animals.[55] This may be related to a loss of muscle mass and a reduction in the rate of formation of creatinine rather than any effect of thyrotoxicosis on tubular secretion of creatinine, because this is not considered to occur in cats. Whatever the cause of decreased creatinine concentrations, it is likely that this effect will tend to mask evidence of renal failure in cats. This has implications when assessing renal function in hyperthyroid cats prior to deciding on the best option for treatment (see Effect of Treatment on Renal Function).

1549

A number of other clinicopathologic abnormalities have been described in hyperthyroid cats. Clinically significant hypokalemia has been reported in four hyperthyroid cats, but the cause remains unclear.[33] Blood glucose concentrations may be increased in small number of hyperthyroid cats, presumably reflecting a stress response.[6,9] Hyperthyroidism is also associated with glucose intolerance characterized by delayed clearance of administered glucose from the plasma despite increased secretion of insulin.[56] This is not reversible after treatment, which may be related to weight gain as euthyroidism is achieved. Two separate studies have examined the effect of hyperthyroidism on circulating fructosamine concentration.[57,58] In both studies, serum fructosamine concentration was significantly lower in hyperthyroid compared with healthy cats, presumably as a result of increased protein turnover. Importantly, as many as 50% of cats had values

below the respective reference range. Caution is therefore advised in interpreting serum fructosamine concentration in hyperthyroid cats, particularly if concurrently diabetic. Other biochemical parameters such as cholesterol, sodium, chloride, bilirubin, albumin, and globulin are usually within their respective reference ranges in hyperthyroid cats unless affected by a concurrent nonthyroidal illness. Urinalysis is generally unremarkable. The urine specific gravity (USG) is extremely variable, ranging from 1.009 to 1.050, but is generally lower than in an age-matched population, presumably reflecting the effect of hyperthyroidism on renal concentrating mechanisms.[6,9,55]

239.1.3.4 Thyroid Function Tests

The diagnosis of hyperthyroidism is confirmed by the demonstration of increased production of the thyroid hormones or thyroidal radioisotope uptake.

239.1.3.4.1 Pathophysiology

In cats, T_4 rather than T_3 is the main secretory product of the thyroid gland. However, T_3 is three to five times more potent than T_4. Most circulating T_3 is produced from extrathyroidal 5′-deiodination of T_4 and, as a result, T_4 is often considered as a prohormone, and activation to T_3 a step that is autoregulated by peripheral tissues. Over 99% of circulating T_4 is protein bound, the remainder is free and metabolically active. Overall control of thyroid function is mediated via the negative-feedback effect of circulating T_4 and T_3 on thyrotropin-releasing hormone (TRH) from the hypothalamus and TSH from the anterior pituitary.

239.1.3.4.2 Basal circulating thyroid hormone concentrations

Increased basal circulating concentrations of total T_4 and T_3 concentrations are the biochemical hallmarks of hyperthyroidism and are extremely specific for its diagnosis. However, since the first reports of the disease, it has been recognized that although circulating total T_4 and T_3 concentrations are highly correlated, measurement of circulating total T_4 is preferable.[6,29] In early studies, a small percentage (< 10%) of cats with elevated circulating total T_4 concentrations had concurrent reference range total T_3 values. This has increased to approximately one third of cats tested in more recent reports (Figure 239-1).[9,59] Severe concurrent nonthyroidal illness may play a role in suppressing T_3 concentration by inhibiting peripheral conversion of T_4 to T_3, as it does in humans, although this appears to be a less common phenomenon in cats.[29] The majority of hyperthyroid cats with total T_3 concentration within reference range are classified as mildly affected, with only mild abnormalities in circulating T_4 concentration. It is likely that the total T_3 concentration would increase into the reference range if the disorder were allowed to progress untreated.[6]

Early reports suggested that all hyperthyroid cats had elevated total T_4 concentrations with values up to 19 times the upper limit of the reference range.[6,29] However, it has recently been recognized that up to 10% of hyperthyroid cats have reference range circulating total T_4 concentrations (Figure 239-2).[9,59] Such values are usually, but not exclusively, within the mid-to high end of the reference range.

Hyperthyroidism, therefore, should not be excluded based on finding a single reference range total T_4 value.

Nonspecific fluctuation of thyroid hormones has been reported in hyperthyroid cats and may account for the reference range total T_4 values found. In cats with markedly elevated serum thyroid hormone concentrations, the degree of fluctuation is of little diagnostic significance.[60,61] However, in mildly affected cats with marginally elevated total T_4 values, the degree of fluctuation can result in reference range values.[61] Increased thyroidal production could result in increased circulating concentration, but because the serum half-life of thyroid hormones is measured in hours, acute decreases presumably reflect fluctuations in binding proteins or other unclear hemodynamic changes. If mild hyperthyroidism is suspected in a cat with mid-to high reference range circulating total T_4 concentration, a repeat measurement is indicated. Because the degree of fluctuation is greater over a period of days than hours, further sampling should be deferred for 1 or 2 weeks.[1,61]

1549

1550

Figure 239-1 Box plots of serum total triiodothyronine (T_3) concentrations in 172 clinically normal cats, 917 cats with untreated hyperthyroidism, and 221 cats with nonthyroidal disease (other illness). The box represents the interquartile range (i.e., 25% to 75% range or the middle half of the data). The horizontal bar in the box represents the median value. For each box plot, the T-bars represent the main body of the data, which in most instances is equal to the range. Open circles represent outlying data points. The shaded area indicates the reference range for serum T_3 concentration. To convert serum T_3 concentrations from nmol/L to ng/dL, one should divide the given values by 0.0154. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal illness. J Am Vet Med Assoc 218:529, 2001.)

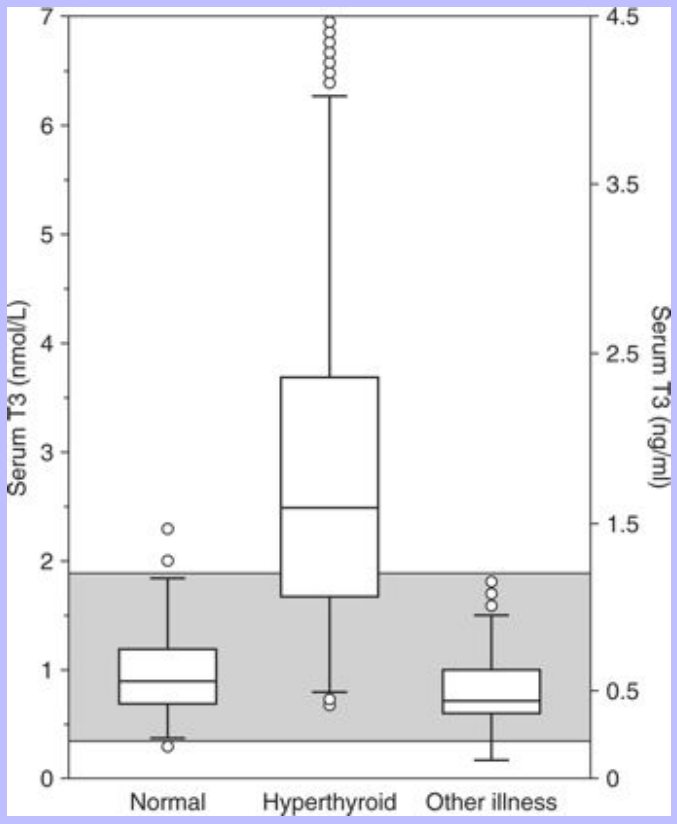

Figure 239-2 Box plots of serum total thyroxine (T_4) concentrations in 172 clinically normal cats, 917 cats with untreated hyperthyroidism, and 221 cats with nonthyroidal disease (other illness). Data are plotted (i.e., box plots) as described in the legend of Figure 239-1. The shaded area indicates the reference range for serum T_4 concentration. To convert serum T_4 concentrations from nmol/L to ng/dL, divide the given values by 12.87. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal illness. J Am Vet Med Assoc 218:529, 2001.)

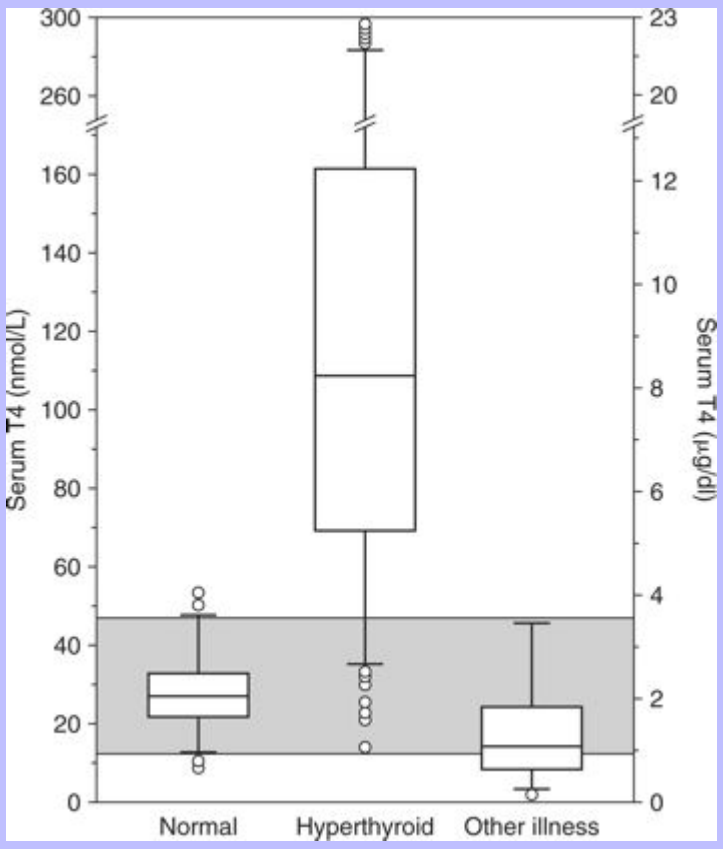
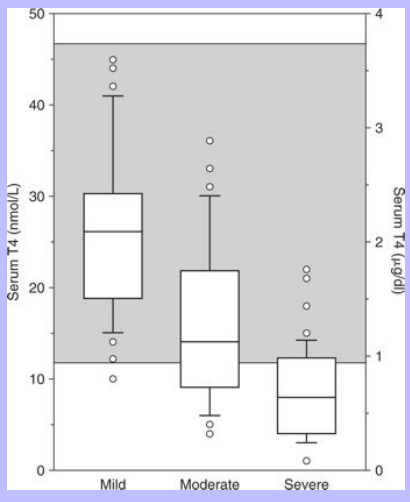


Nonthyroidal illness is capable of suppressing circulating total T_4 concentration in cats as in dogs. The degree of suppression is correlated to the severity rather than the type of illness; because it is inversely correlated to mortality, it can be used as a prognostic indicator (Figure 239-3).[59,62,63] The mechanisms

remain unclear but are more likely to involve changes in protein binding or metabolism rather than any effect on the hypothalamic-pituitary-thyroid axis.[62,63] Similar suppression occurs in hyperthyroid cats with concurrent nonthyroidal illness. The degree of suppression has little diagnostic significance in hyperthyroid cats with markedly elevated serum total T_4 concentration.[29,62,64] However, in cats with mild or early hyperthyroidism, reference range circulating total T_4 concentrations may occur. In the largest study of 917 hyperthyroid cats, a concurrent illness was identified in 17 of 80 (22%) cats with mild hyperthyroidism and reference range serum total T_4 concentration.[59] In the majority of affected cats, serum total T_4 concentration is within the mid-to high end of the reference range. Occasionally, values are within the mid-to low end of the reference range, but such cats usually exhibit the most severe concurrent illnesses. Other signs, particularly detection of a palpable thyroid nodule, may indicate the need to further investigate hyperthyroidism in such cats.[59] Serum total T_4 values will increase into the thyrotoxic range upon stabilization of or recovery from the nonthyroidal illness.[1,62]

Figure 239-3 Box plots of serum total thyroxine (T_4) concentrations in 221 cats with nonthyroidal disease (other illness), grouped according to severity of illness. Of the 221 cats, 65 had mild disease, 83 had moderate disease, and 73 had severe disease. Data are plotted (i.e., box plots) as described in the legend of Figure 239-1. The shaded area indicates the reference range for serum T_4 concentration. To convert serum T_4 concentrations from nmol/L to ng/dL, one should divide the given values by 12.87. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal illness. J Am Vet Med Assoc 218:529, 2001.)



Measurement of circulating free T_4 concentration may provide an alternative means of diagnosing hyperthyroidism, particularly in cats with reference range total T_4 values. In humans, free T_4 measurement is considered a superior diagnostic test for hyperthyroidism because it is less affected by nonthyroidal factors than is total T_4 and provides a more accurate reflection of thyroid status.[65] Notably, when serum total T_4 concentration is increased, the concentration of free T_4 is disproportionately increased. This may be related in part to relative saturation of binding proteins by T_4 and subnormal concentration of the principle binding proteins.[65] In addition, serum free T_4 concentration remains increased in hyperthyroid patients with nonthyroidal illnesses when total T_4 concentration is suppressed into the reference range.[65] Measurement of free T_4 concentration has recently been evaluated in a large number of hyperthyroid cats and as in humans, appears to be an extremely sensitive diagnostic test (Figure 239-4).[59] In this study, serum free T_4 concentration was elevated in 903 (98.5%) of 917 hyperthyroid cats, whereas corresponding serum total T_4 values were elevated in only 837 (91.3%) cases. However, in all cats with an elevated serum total T_4 concentration, free T_4 concentration is concurrently high.[59] Thus measurement of free T_4 concentration offers no further diagnostic information. However, in 205 hyperthyroid cats categorized as mildly affected with or without a concurrent illness, serum total T_4 concentration was only elevated in 125 (61%) cases, whereas corresponding free T_4 concentrations were high in 191 (93.2%) cats (Figure 239-5). Free T_4 analysis is not without disadvantage. It is only reliably measured by methods involving dialysis that increase expense and are not always readily available.[1] In addition, it lacks diagnostic specificity compared with total T_4 measurement. In two separate studies, 6% to 12% of sick euthyroid cats had elevated circulating free T_4 concentrations.[29,59] These cats generally had corresponding total T_4 values in the lower half of or below the reference range. Serum free T_4 concentration should therefore be interpreted with caution if used as the sole diagnostic criterion for confirmation of hyperthyroidism. It is more reliable if interpreted together with a serum total T_4 concentration. A mid-to high reference range total T_4 and elevated free T_4 concentration is consistent with hyperthyroidism.[59] By contrast, low total T_4 and elevated free T_4 values are usually associated with nonthyroidal illness.[29,59]

1550
1551

Identification of concurrent nonthyroidal illness, repeat total T_4 analysis or simultaneous free T_4 measurement usually provides enough evidence to confidently diagnose hyperthyroidism. However, dynamic thyroid function tests have been recommended as helpful in achieving a diagnosis. The methods for performing these tests are outlined in Table 239-2. Realistically they should be reserved for cats with clinical signs suggestive hyperthyroidism when repeated total T_4 concentration remains equivocal and serum free T_4 measurement is unavailable or unhelpful.[65]

239.1.3.4.3

Thyroid-stimulating hormone response test

In an early study it was suggested that the TSH response test was useful in confirming a diagnosis of hyperthyroidism because there was little difference in serum concentrations of T_4 before and after exogenous TSH administration.[6] In a larger study of 40 hyperthyroid cats, including those with

equivocal total T_4 values, the overall limited T_4 response to TSH stimulation was confirmed.[66] However, it was shown that hyperthyroid cats with equivocal basal total T_4 concentrations exhibit a response 1551
indistinguishable from that in healthy cats, suggesting that the abnormal thyroid glands do retain the 1552
ability to respond to TSH but are producing T_4 at maximal rates. Presumably hyperthyroid cats with the lowest basal total T_4 concentration have the greatest potential to respond to TSH, although it has been suggested that this response may be related to stimulation of normal thyroid tissue often found within hyperplastic glands.[66] Bovine TSH has traditionally been used for the TSH response test but is no longer commercially available as a pharmaceutical preparation. Recombinant human TSH has been evaluated in euthyroid cats and appears to be a safe and effective replacement for bovine TSH.[67] However, TSH is expensive and because of the difficulties in interpreting the test results, the TSH response test has significant limitations in the evaluation of hyperthyroidism in cats.

Figure 239-4 Box plots of serum free thyroxine (T_4) concentrations in 172 clinically normal cats, 917 cats with untreated hyperthyroidism, and 221 cats with nonthyroidal disease (other illness). Data are plotted (i.e., box plots) as described in the legend of Figure 239-1. The shaded area indicates the reference range for serum free T_4 concentration. To convert serum free T_4 concentrations from nmol/L to ng/dL, one should divide the given values by 12.87. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal illness. J Am Vet Med Assoc 218:529, 2001.)

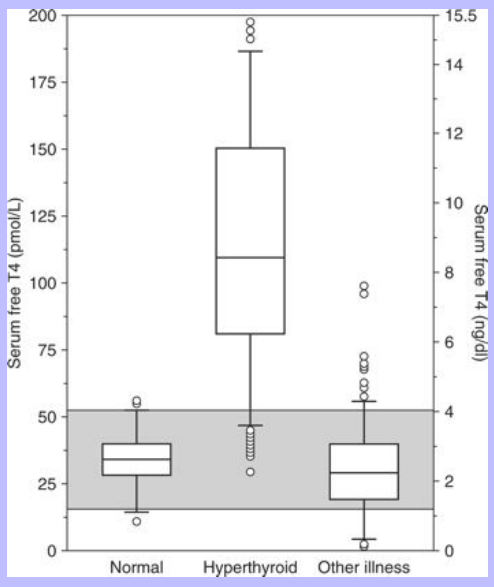


Figure 239-5 Box plots of serum total thyroxine (T_4), total triiodothyronine (T_3), and free T_4 concentrations in 205 cats with mild hyperthyroidism (defined as total T_4 concentration < 66 nmol/L). Data are plotted (i.e., box plots) as described in the legend of Figure 239-1. The shaded area indicates the reference range for each hormone. (From Peterson ME et al: Measurement of serum concentrations of free thyroxine, total thyroxine, and total triiodothyronine in cats with hyperthyroidism and cats with nonthyroidal illness. J Am Vet Med Assoc 218:529, 2001.)

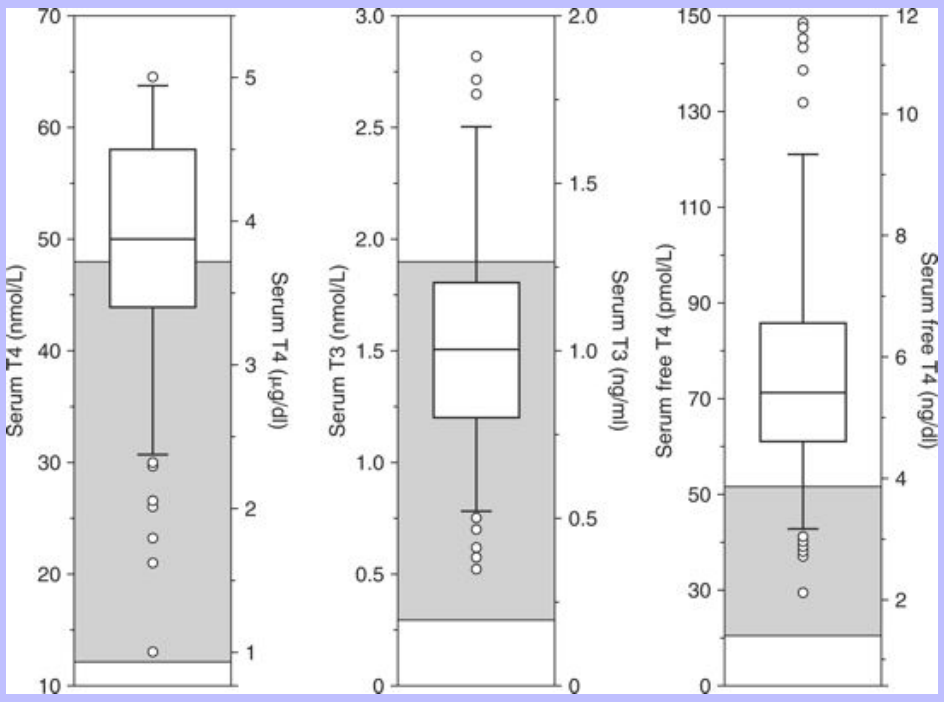

Table • 239-2 Protocols for Dynamic Thyroid Function Tests Used for Diagnosing Hyperthyroidism in Cats

TEST	TSH RESPONSE		TRH RESPONSE	T_3 SUPPRESSION
Drug	Bovine TSH	Recombinant human TSH*	TRH†	Liothyronine‡
Dose	0.5 IU/kg	0.025–0.20 mg/cat	0.1 mg/kg	15–25 g every 8 hours for 7 doses
Route	Intravenous	Intravenous	Intravenous	Oral
Sampling times	Zero and 6 hours	Zero and 6–8 hours	Zero and 4 hours	Zero and 2–4 hours after last dose
Assay	Total T_4	Total T_4	Total T_4	Total T_4 and total T_3

239.1.3.4.4 Thyrotropin-releasing hormone response test

In healthy cats, administration of TRH causes an increase in TSH and, in turn, thyroid hormone secretion. In hyperthyroidism, this pathway is less functional because of chronic TSH suppression from autonomous thyroid hormone production. A significant increase occurs in mean serum total T_4 concentration after TRH administration in healthy and hyperthyroid cats and those with nonthyroidal illness.[68] However, the percentage increase in total T_4 is considerably less in the hyperthyroid cats compared with healthy cats and those with other diseases. It has been suggested that a relative increase in total T_4 of less than 50% is consistent with mild hyperthyroidism, a value greater than 60% is suggestive of euthyroidism, and values between 50% and 60% remain equivocal.[68] Similar to the TSH response test, measurement of total T_3 concentration is unhelpful because of the greater variability in response both within and between healthy and sick cats.[66,68] Adverse reactions to TRH administration appear to be common, occurring within minutes of administration. Adverse reactions include vomiting, excessive salivation, tachypnea, and defecation. TRH possibly evokes these effects indirectly, via activation of central cholinergic and catecholaminergic mechanisms and directly, via central TRH-binding sites.[1] However, although these reactions are transient and usually resolve within hours, the diagnostic accuracy of the TRH response test has recently been questioned. Results of the TRH response test are largely indistinguishable between sick euthyroid and hyperthyroid cats with concurrent nonthyroidal illness and total T_4 concentrations within or below the reference range, thereby limiting its diagnostic usefulness.[69]

239.1.3.4.5 Triiodothyronine-suppression test

The T_3 suppression test relies on the ability of administered liothyronine, through negative feedback, to decrease T_4 production by the thyroid gland. In hyperthyroidism, because excess circulating thyroid hormone concentrations have already suppressed TSH production and secretion, additional T_3 has minimal effect on T_4 production. Therefore serum total T_4 concentration remains significantly higher

after liothyronine administration in hyperthyroid compared with euthyroid (both healthy and sick) cats, and the percentage decrease is consequently significantly lower.[70,71] Although individual laboratories vary, as a general guideline, postliothyronine serum total T_4 concentration tends to be greater than 20 nmol/L in hyperthyroid cats and less than 20 nmol/L in euthyroid cats (Figure 239-6). A greater overlap of results is seen in hyperthyroid and euthyroid cats when percentage change in total T_4 is calculated. However, suppression of 50% or more is consistent with euthyroidism, whereas hyperthyroid cats rarely have values exceeding 35%. Although the T_3 suppression test is a potential aid for confirming the diagnosis of hyperthyroidism, it has been suggested to be most useful in confirming euthyroidism and ruling out hyperthyroidism.[70] Unlike the TRH response test, it is not associated with any adverse reactions. However, it is a relatively prolonged test and highly dependent on good owner compliance in reliably administering liothyronine tablets and adequate GI absorption (necessitating confirmation by pre-and postserum total T_3 measurement).[7,70] If a dynamic thyroid function test is deemed necessary to investigate hyperthyroidism in a cat, the T_3 suppression test is preferred (given the problems of both the TSH and TRH response tests).

239.1.3.4.6

Thyroid radionuclide uptake and imaging

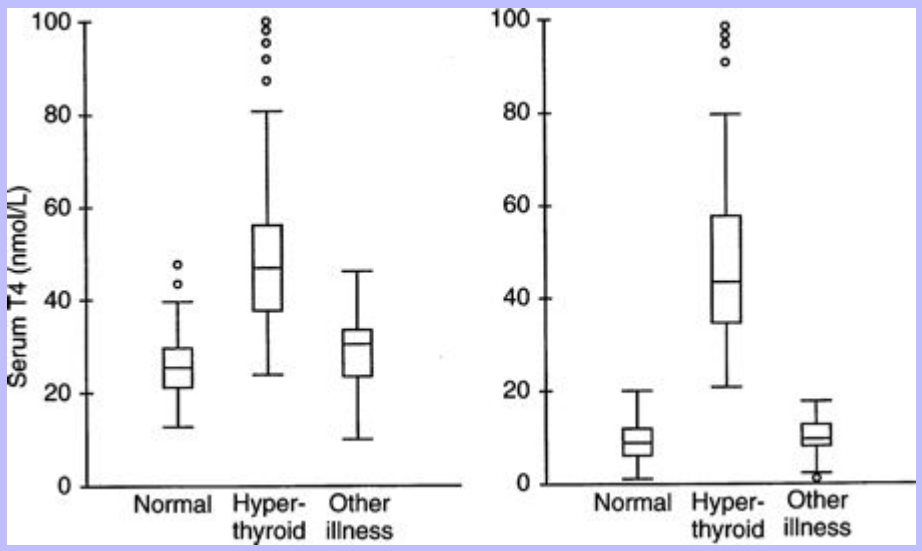
Hyperthyroid cats usually exhibit increased uptake of radioactive iodine (as ^{131}I or ^{123}I) or technetium-99m as pertechnetate ($^{99m}TcO_4^-$).[6,72–75] Percentage uptake of $^{99m}TcO_4^-$ or increased thyroid: salivary ratio at 20 minutes are strongly correlated with circulating thyroid hormone concentrations.[73,75] Preliminary studies suggest that $^{99m}TcO_4^-$ scans are a more sensitive means of diagnosing hyperthyroidism than basal thyroid hormone analyses or TRH response test results, but further studies are required in this area.[76,77] Care should be taken in interpreting uptake results in cats recently treated with antithyroid drugs. Radioisotope uptake is increased in healthy cats treated with methimazole with significant enhancement after drug withdrawal, and presumably the latter situation may exist in hyperthyroid cats.[78]

Determining percent uptake of radioisotopes is expensive and requires access to sophisticated equipment. However, qualitative scintigraphic imaging remains a useful procedure to determine unilateral or bilateral lobe involvement, alterations in the position of the thyroid lobes, the site of hyperfunctioning ectopic or accessory tissue, or distant metastases from a functioning thyroid carcinoma.[5] For such imaging $^{99m}TcO_4^-$ is preferred. It has a more rapid uptake and half-life; scanning can commence within minutes rather than hours, allowing for more rapid completion. In addition, higher doses can be used without delivering a high radiation dose, and the quality of the scans is consistently equal or superior to that when radioactive iodine is used.[5]

1552

1553

Figure 239-6 Box plots of the serum total thyroxine (T_4) concentrations before **(A)** and after **(B)** administration of liothyronine to 44 clinically normal cats, 77 cats with hyperthyroidism, and 22 cats with nonthyroidal disease. Data are plotted (i.e., box plots) as described in the legend of Figure 239-1. To convert serum T_4 concentrations from nmol/L to ng/dL, one should divide the given values by 12.87. (From Peterson ME et al: Triiodothyronine suppression test. An aid in the diagnosis of mild hyperthyroidism in cats. J Vet Intern Med 4:233, 1990.)



239.1.4 Treatment

Spontaneous remission of hyperthyroidism does not occur, and prevention is not possible because the cause is unknown. Failure to institute therapy will result in insidious progression to emaciation, severe metabolic and cardiac dysfunction, and ultimately death. However, because of the benign nature of the thyroid lesions, the disease carries a favorable prognosis with effective therapy. Treatment of hyperthyroidism is aimed at removing or destroying abnormally functioning thyroid tissue, pharmacologic inhibition of thyroid hormone synthesis, and release or amelioration of the influence of excess thyroid hormones on peripheral tissue. Surgical thyroidectomy or thyroid ablation using radioactive iodine are the only reasonable curative methods available. Medical management is noncurative; because of this, it is not recommended alone in the rare cases of functioning thyroid carcinoma.

Each treatment method has its own advantages and disadvantages. No one therapy can be recommended above another for all cats. The selection must be individualized for each cat, taking into account several factors including age, severity of thyrotoxicosis, presence of concurrent illnesses, facilities available, potential complications, cost, and the owner's willingness to accept the form of treatment advised.

239.1.4.1 Antithyroid Drugs and Other Medical Treatments

Numerous pharmacologic agents may be used in the medical management of feline hyperthyroidism. Indications, dose regimens, potential adverse reactions, and contraindications are summarized in Table 239-3. Chronic medical management is a practical treatment option for hyperthyroidism that requires no special facilities, is readily available, easy to implement, and reasonably inexpensive. Almost all cats are potential candidates, because unless it is suspected of thyroid carcinoma, few specific contraindications exist. When thyroid hormone production or secretion is inhibited, generally a rapid return to euthyroidism occurs. Anesthesia is avoided, as are the peri-and postoperative complications associated with surgical thyroidectomy. Unlike radioactive iodine therapy, hospitalization is unnecessary. On the other hand, few drugs are available for long-term control, daily medication is necessary, and a real risk of poor compliance exists (by the owner, the cat, or both) in regularly administering and accepting the medication. This impinges on efficacy and cost because it necessitates more frequent monitoring. In addition the development of adverse reactions may necessitate drug withdrawal; therefore not all cats initially managed medically can be maintained long-term with this form of therapy. A further consideration is that relapse of hyperthyroidism invariably occurs within 24 to 72 hours after drug withdrawal.[52,79] Although often considered a disadvantage, it may prove beneficial in cats that develop overt renal failure upon induction of euthyroidism (see Effect of Treatment on Renal Function).

Pharmacologic intervention is also necessary prior to surgical thyroidectomy to decrease the metabolic and cardiac complications associated with thyroid hormone excess. In addition, it may be desirable to provide some control, at least clinically, while awaiting radioactive iodine administration.

239.1.4.1.1 Thioureylene antithyroid drugs

The thioureylene antithyroid drugs include propylthiouracil, methimazole, and carbimazole. These drugs are actively concentrated by the thyroid gland and act as general inhibitors of thyroid peroxidase-catalyzed reactions including oxidation of iodide and iodination of tyrosyl residues in thyroglobulin. They also interfere with the coupling of iodotyrosines to iodothyronines via inhibition of thyroid peroxidase or by binding to and altering the structure of thyroglobulin, a reaction more sensitive to inhibition than the formation of iodotyrosines. The trapping of inorganic iodide by, or the release of preformed hormones from, the thyroid gland is not affected by these drugs.[1,52,78,79]

The thioureylene antithyroid drugs are the therapeutic mainstay in the medical management of both human and feline hyperthyroidism because of their consistent effect in lowering serum thyroid hormone concentrations. They are widely recommended to stabilize hyperthyroid cats prior to surgery and are the only drugs that can be used chronically for management of hyperthyroidism. Propylthiouracil is the least potent but is widely available and has an additional advantage of inhibiting peripheral T_3 production. However, it is associated with an unacceptably high incidence of serious hematologic complications in both healthy and hyperthyroid cats; therefore it is no longer recommended for use in this species.[65]

Methimazole is available in the United States (Tapazole, Jones Medical Industries) and is specifically licensed for use in hyperthyroid cats in the United Kingdom (Felimazole, Arnolds Veterinary Products Limited). Elsewhere, methimazole or carbimazole is variably available. Carbimazole is a carbethoxy derivative of methimazole and was originally developed in the hope of obtaining a drug with a longer duration of activity than methimazole for human use. Although possessing inherent antithyroid activity,

it exerts its antithyroid effect through immediate conversion to methimazole when administered orally.[80] Serum concentrations of methimazole achieved after carbimazole administration are less than after administration of an equal weight of methimazole, reflecting the molar ratio of the two drugs. This conversion results in a 5 mg dose of carbimazole being approximately equivalent to 3 mg of methimazole and may account for the slight differences in dose regimes recommended for the two drugs.[52,79] However, given the reduction in severity of thyrotoxicosis in cats seen currently, such differences have become less noticeable.

Table • 239-3 Indications, Doses, Adverse Reactions, and Contraindications for the Drugs Commonly Used to Manage Hyperthyroidism

DRUG	INDICATIONS	DAILY DOSE	ADVERSE REACTIONS	CONTRAINDICATIONS
Methimazole andcarbimazo le	Prior to surgery (2–3 weeks)	5–15 mg divided two or three times daily	Vomiting, anorexia, depression; facial excoriations; hematologic complications; hepatopathy	If adverse reactions occur; at the time of radiotherapy
	Chronic management	5–10 mg once or divided twice daily		
Propranolol	Symptomatic control	7.5–15 mg divided three times daily	Bradycardia, myocardial depression; bronchospasm; diarrhea	Asthma, uncontrolled heart failure; chronic management
Atenolol		6.25–12.5 mg once or twice daily		Chronic management
Propranolol with potassium iodate	Prior to surgery (3 weeks)	7.5–15 mg divided three times daily, days 1–21	Anorexia, depression, vomiting	Chronic management; immediately prior to ^{131}I therapy
		63.75 mg divided three times daily, days 11–20		
Calcium ipodate	Prior to surgery (up to 14 weeks)	100 mg divided twice daily	None	Chronic management

Pharmacological studies in healthy cats have shown that methimazole has good oral bioavailability with a serum half-life of between 4 and 6 hours.[81,82] After multiple-dose administration of methimazole, some evidence of drug-induced accelerated metabolism is seen; however, this has not been borne out by clinical studies.[82] Most pharmacokinetic parameters of methimazole in cats are not significantly altered by hyperthyroidism; although a trend toward faster elimination exists, this is not considered to be clinically important.[81]

Initially, methimazole should be administered orally at a dose of 10 to 15 mg/day, in divided doses every eight to 12 hours, depending on the severity of the thyrotoxicosis.[79] Carbimazole has been recommended at an initial oral dose of 15 mg, divided three times daily.[52] Attainment of biochemical euthyroidism is relatively rapid, occurring in a mean of approximately 6 days at least for carbimazole.[52] Not surprisingly the length of therapy is correlated with the basal serum total T_4 concentration. As cats are diagnosed with hyperthyroidism earlier, the trend toward using only twice-daily administration of low doses (2.5 to 5

mg) of carbimazole or methimazole increases.[83] Once-daily dosing, however, appears less effective in inducing euthyroidism.[83] For practical purposes, the initial dose is prescribed for a period of 2 to 3 weeks, which allows time for more obvious clinical improvement and ensures the attainment of euthyroidism in over 90% of cats.[52,79] At that time, a circulating total T_4 concentration is measured and, if within or below the reference range, surgery can be performed (administering the last dose on the morning of surgery). For severely affected cats, although biochemical euthyroidism is rapidly achieved, a longer course of preoperative therapy may be beneficial before the patient is considered a reasonable surgical candidate. In such cases, the dose is adjusted as in cats in which medical management has been selected as the sole therapy. If euthyroidism is not achieved within this initial period, the duration of therapy is increased or the dose altered in 2.5 to 5 mg increments. Rarely doses as high as 25 to 30 mg of methimazole are required to restore euthyroidism.[1,7,79] Lack of owner or cat compliance should be excluded as a possible reason for failure of therapy. Documenting a decline in the activities of the liver enzymes provides an inexpensive but nonspecific alternative to monitoring serum total T_4 concentration when assessing therapeutic efficacy.[52]

1554

For long-term therapy, once euthyroidism has been achieved, the daily dose is adjusted in 2.5 to 5 mg decrements, aiming for the lowest possible dose that effectively maintains euthyroidism. 1555 Further dose adjustments are based on circulating total T_4 concentrations assessed every 2 to 3 weeks until stable and every 3 to 6 months thereafter or as indicated clinically. Most cats require 10 mg methimazole per day, whereas a few require doses as high as 15 to 20 mg/day or as low as 2.5 to 5 mg/day.[79] Although divided doses are most successful in treating hyperthyroid cats (and despite the relatively short serum half-life), the intrathyroidal residence time may be approximately 20 hours as it is in humans. When owner compliance is problematic, once-daily dosing may prove effective chronically, although this has not been fully evaluated. Further increasing the time between dosing results in recurrent hyperthyroidism.[52,79] Carbimazole appears to be most effective if chronically administered at a dose of 5 mg twice daily.[52]

In many cats, such antithyroid therapy results in serum total T_4 concentrations below the reference range. However, clinical signs of hypothyroidism do not develop, and surgical risks are not increased. Corresponding serum total T_3 concentrations tend to remain within the reference range, and euthyroidism is maintained because T_3 is more metabolically active than T_4.[52] This may result from increased extrathyroidal T_4 to T_3 conversion or increased thyroidal secretion of T_3 because of intrathyroidal iodine deficiency or increased TSH production. In addition, serum free T_4 concentration, representing the active portion of T_4, appears to remain relatively higher than total T_4 concentration during methimazole therapy.[65] As a result, the aim is to suppress total T_4 into the lower half of the reference range; however, if severely depressed, the dose should be adjusted and the cat retested because at least some adverse reactions appear to be dose related.[79]

Methimazole and carbimazole have no effect on the underlying pathologic lesion in hyperthyroid cats. Thus over months to years of treatment, the thyroid nodule or nodules can continue to grow and enlarge. As a result it is common for the daily dose of antithyroid drugs to progressively increase. Some cats may no longer adequately respond to methimazole or carbimazole, and an alternative form of therapy is necessary.[1]

Although antithyroid dugs are routinely administered orally, compliance can be problematic in fractious or inappetant cats; absorption is potentially adversely affected by concurrent intestinal disease, and obvious difficulties exist in cats that vomit. Preliminary studies have shown that methimazole in a pluronic lecithin organogel (PLO) is effective in hyperthyroid cats when applied transdermally. However, subsequent studies of healthy cats have demonstrated poor bioavailability by this route, and further studies are required before widespread recommendation.[84]

Most clinical adverse reactions associated with methimazole or carbimazole occur within the first 3 months of therapy. They include vomiting, with or without anorexia and depression, usually within the first 4 weeks of therapy (occurring in 10% to 15% of cases).[52,79] These effects are more common with methimazole and may be related to its unpleasant bitter taste (compared with carbimazole, which is tasteless). However, these signs are usually transient and rarely require withdrawal of the drug. Self-induced excoriations of the head and neck have been seen in a small number of cats treated with methimazole or carbimazole within the first 3 months of therapy.[65,79] Drug withdrawal is usually required together with glucocorticoid therapy, and an alternative treatment for the hyperthyroidism is necessitated.

Early in the course of therapy, mild hematologic complications of eosinophilia, lymphocytosis, and leukopenia (with a normal differential count but without apparent clinical effect) occur in up to 16% of cases treated with methimazole and only 5% of cases treated with carbimazole.[52,79] More serious hematologic complications occur in less than 5% of cats treated with methimazole and include agranulocytosis and thrombocytopenia, either alone or concurrently, or more rarely, immune-mediated hemolytic anemia (usually occurring within the first 3 months of therapy).[7,79] These are apparently not dose related. While rarely reported for carbimazole, these worrisome problems can and do occur anecdotally. To predict such reactions, complete blood count (CBC) and platelet count is recommended every 2 weeks at least initially.[1,79] However, this is not cost-effective because of their low frequency and unpredictable occurrence. Therefore testing, if and when clinical signs develop, is more appropriate. There may however, be some merit in checking cats prior to surgery, particularly because thrombocytopenia is a potential risk.[1] Hepatic toxicity, exemplified by marked increases in the liver enzymes and bilirubin concentration, has also been described in less than 2% of cats treated with methimazole.[79] Cessation of therapy is required if either serious hematologic or hepatic reactions develop.

Serum antinuclear antibodies develop in approximately 50% of cats treated with methimazole for longer than 6 months, usually in cats on high-dose therapy (> 15 mg/day).[79] Although clinical signs of a lupuslike syndrome have not been reported, decreasing the daily dose is usually recommended. Such studies have not yet been carried out for carbimazole. A bleeding tendency without associated thrombocytopenia has been suggested to occur in cats treated with methimazole.[65] However, methimazole therapy had no effect on prothrombin time (PT) or activated partial thromboplastin time (APTT) after over 12 weeks of therapy, and it had no effect on thrombin clotting time or buccal mucosal bleeding time after 3 to 4 weeks of therapy in hyperthyroid cats.[85,86] However, a prolonged proteins induced by Vitamin K antagonism or absence (PIVKA) clotting time, together with melena, was reported in one cat, and this test is considered a more sensitive indicator of potential or actual bleeding tendencies than either PT or APTT.[86] Acquired myasthenia gravis (MG) and a cold agglutinin-like disease have been described in a few cats treated with methimazole.[1]

Editor's Note: There are numerous protocols for medical management of hyperthyroidism in cats. Our current recommendation is to administer 2.5 mg of methimazole orally once daily (or 2.0 mg of topical methimazole once daily) for 2 weeks. After this 2 week period, if the owners note any improvement or deterioration in their cats' condition, a serum total T_4 (with or without a CBC, serum biochemistry profile and urinalysis) should be obtained 4 to 6 hours after methimazole administration. If the value is within reference limits, that dose should be continued indefinitely. If neither improvement nor deterioration is appreciated or if the serum total T_4 concentration remains abnormally increased, the medication should be given BID for an additional 2 weeks. The cat should then be rechecked and the dose increased in 2 mg (topically) or 2.5 (orally) increments every 2 weeks, as needed. If administered topically, owners should be instructed to thoroughly rub the medication into the skin and then remove all excess vehicle within 30 minutes of each dose. If any abnormalities are detected that could be the result of methimazole, its' use should be discontinued until it can be demonstrated that continued use of the drug is warranted. It is further recommended that topical methimazole be compounded so that each dose is 0.05–0.10 cc this limits the problem of excess vehicle building upon the ears.

239.1.4.1.2

Other medical treatments

The thioureylene antithyroid drugs are preferred for the treatment of hyperthyroidism, but there may be occasions when alternatives are required either because of the development of adverse reactions or other specific contraindications. However, chronic management is only achieved with methimazole or carbimazole. Beta-adrenergic blockers, stable iodine, and calcium ipodate only provide short-term control, and a more permanent treatment option is subsequently required.

Propranolol (Inderal, Wyeth-Ayerst) and atenolol (Tenormin, ICI Pharma) are the most frequently used beta-blockers in hyperthyroid cats. They are usually used to symptomatically control the tachycardia, polypnea, hypertension, and hyperexcitability associated with hyperthyroidism and to prevent the arrhythmias that may occur when anesthetizing affected cats.[1] Traditionally these drugs were considered to have no direct effect on the thyroid gland or thyroid hormones; however, propranolol, at least, may inhibit peripheral conversion of T_4 to T_3 in cats as in humans.[87] They are usually used in combination with antithyroid drugs when rapid control of the clinical effects is required or with stable iodine to ensure a more effective response.[1,87] Because they do not affect uptake of radioactive iodine, they may be useful while awaiting such therapy or in cats that have a delayed return to euthyroidism after treatment.[1]

1555
1556

Propranolol is a nonselective beta-adrenergic receptor–blocking agent and is therefore contraindicated in cats with asthma or pre-existing uncontrolled overt CHF. Atenolol, as a selective beta1 adrenoceptor–blocking agent is more useful in some of these situations and has the added advantage of a potential once-daily dosing regime. Propranolol is administered initially at a dose of 2.5 to 5 mg every 8 to 12 hours and subsequently titrated based on clinical effects and reduction in heart rate. Hyperthyroidism affects the pharmacokinetic profile of propranolol, and as such, low doses are recommended initially.[88] Atenolol is administered at a dose of 6.25 mg/cat either once or twice daily.

Large doses of stable iodine acutely decrease the rate of thyroid hormone synthesis (Wolff-Chaikoff effect) and thyroid hormone release. The mechanisms are unclear but are presumed to be protective. Its effects on reducing the vascularity and friability of thyroid tissue are controversial. Use of stable iodine has never gained widespread popularity because of its inconsistent, short-lived, and erratic effect in

inducing euthyroidism and the potential for escape from inhibition and exacerbation of thyrotoxicosis. In addition, it is contraindicated prior to radioactive iodine administration and is associated with a high incidence of adverse reactions (salivation and partial to complete anorexia), purportedly because of its unpleasant brassy taste.[1,7] However, a recent report has suggested using potassium iodate tablets together with propranolol in a staged regime for 20 days before surgery.[87] Propranolol is administered at a dose of 2.5 mg three times daily for 20 days before surgery, titrated to effect, and potassium iodate is administered at a dose of 21.25 mg three times daily from the tenth to the twentieth day. Using such a regime, serum total T_3 concentration decreases in most cats, and serum total T_4 concentration falls to within reference range in approximately one third of cats. Adverse reactions of potassium iodate are minimized by placing the tablets in a gelatin capsule prior to administration and using a relatively low dose for as short a period as possible. However, despite this, adverse reactions may still occur, albeit less frequently, suggesting a systemic rather than a local effect.[87]

Calcium ipodate, an oral cholecystographic contrast agent, is the only other drug that has been assessed in hyperthyroid cats. Its major effect is to acutely inhibit peripheral T_4 to T_3 conversion. In one study of 12 hyperthyroid cats treated with calcium ipodate at a dose of 100 mg divided twice daily, eight exhibited a good response as indicated by a reduction in serum total T_3 concentration to within the reference range within 2 weeks and an obvious improvement in clinical signs.[89] However, although associated with no adverse reactions, serum total T_4 concentration was unaffected, and cats were not evaluated for longer than 14 weeks. This drug is now of limited availability and further studies are unlikely.

239.1.4.2 Surgical Thyroidectomy

Surgical thyroidectomy is a relatively simple, quick, and curative procedure and is therefore often considered the preferred treatment option in practice. However, to decrease the cardiac and metabolic complications associated with anesthetizing hyperthyroid cats, prior medical management and control of the thyrotoxicosis is required. Once euthyroidism has been achieved, the main surgical considerations are whether to perform a unilateral or bilateral thyroidectomy, the type of technique to use, and the potential postoperative complications.

It is estimated that both thyroid lobes are affected in over 70% of hyperthyroid cats, thereby necessitating a bilateral thyroidectomy. In many of these cats, both thyroid lobes are palpably enlarged, grossly abnormal (or both) on visual examination. However, as many as 15% of cats with bilateral disease have one thyroid lobe that appears grossly normal and if left *in situ* results in recurrent hyperthyroidism usually within 12 months.[90] Thyroid imaging is obviously useful in depicting thyroid lobe involvement, but access to nuclear imaging facilities is required.[5] High resolution ultrasonography, capable of assessing thyroid lobe size and parenchymal appearance, is useful in characterizing thyroid tissue when scintigraphy is not available.[91] In the absence of imaging techniques and as surgical experience increases, many practitioners routinely perform bilateral thyroidectomies regardless of the gross appearance of thyroid lobes.[65] If not routinely attempted, both thyroid lobes must be carefully examined at the time of surgery.

Thyroidectomy can be performed by extracapsular or intracapsular techniques. With extracapsular thyroidectomy, the intact thyroid lobe and capsule is removed after ligation of the cranial thyroid artery while attempting to maintain blood supply to the cranial parathyroid gland. This technique is associated with an unacceptably high prevalence of postoperative hypoparathyroidism and is no longer

recommended.[92] With intracapsular thyroidectomy, the thyroid capsule is incised, the thyroid lobe removed, and the capsule left *in situ*, preserving the blood supply to the cranial parathyroid glands. However, this technique is associated with an unacceptably high risk of recurrence.[90,93] Both techniques have by now been modified to minimize the risk of postoperative hypoparathyroidism and recurrent hyperthyroidism.[92–94] The modified extracapsular technique uses bipolar cautery rather than ligatures, minimizing blunt dissection around the cranial parathyroid gland, whereas the modified intracapsular technique involves removal of the majority of the capsule after dissection. No significant difference is seen in the rate of postoperative hypocalcaemia or recurrence between these two methods, and both are considered equally appropriate for bilateral thyroidectomy in cats.[93] In unilateral cases, the choice of technique is not as important providing recurrence is avoided, because only one parathyroid gland is necessary to maintain eucalcemia.

Hypoparathyroidism resulting in hypocalcemia is the most significant potential postoperative complication. It has been suggested that the osteopenic effects of hyperthyroidism, rapidly reversed after surgical thyroidectomy, may exacerbate hypoparathyroidism in cats as in humans. However, the hyperparathyroidism and tendency toward ionized hypocalcemia reported in hyperthyroid cats suggests that such a phenomenon does not occur in this species.[55] While this in itself may play some role in postoperative hypocalcemia, hypoparathyroidism generally arises only if the parathyroid glands are injured, devascularized, or inadvertently removed during the course of a bilateral thyroidectomy. Revascularization of parathyroid tissue can occur even after removal and subsequent implantation to a nearby muscle belly.[95] Staged thyroidectomies (3 to 4 weeks apart) exploit this premise.[90] A more radical staged simplified complete thyroparathyroidectomy with parathyroid autotransplantation has been described in 10 cats with no postoperative hypocalcemia, which may be of particular benefit as a learning tool or if surgical experience is limited by a small throughput of cases.[65,96] However, a risk of simultaneous transplantation of diseased thyroid tissue exists, and increased costs and risk are associated with two general anesthetic procedures.[90,95]

1556

1557

Mild hypocalcaemia develops in most cats after bilateral thyroidectomy, but treatment is not necessary until clinical signs develop.

Hypoparathyroidism is rarely permanent, and recovery of parathyroid function may occur days to months after surgery. In such cases the parathyroid damage is presumed reversible. Alternatively, accessory parathyroid tissue is activated or more likely, calcium homeostasis is maintained through a PTH-independent mechanism.[97] Other potential postoperative complications include Horner's syndrome, laryngeal paralysis, and voice change, but these are rare.[90]

Circulating thyroid hormone concentrations usually fall below the reference range for weeks to months after thyroidectomy. T_4 supplementation is often recommended, particularly after bilateral thyroidectomy.[1] However, it is not strictly necessary because clinical hypothyroidism is a rare sequelae. Presumably, eventual normalization of thyroid hormone production occurs, either because of activation of the contralateral lobe in unilateral cases or accessory thyroid tissue in bilateral cases. Recurrence of hyperthyroidism is always a possibility after thyroidectomy, and cats should be monitored every 6 to 12 months thereafter. If a unilateral thyroidectomy was originally performed, development of lesions in the contralateral gland should pose no additional surgical risk providing parathyroid function is maintained. However, in cases of recurrent hyperthyroidism after bilateral thyroidectomy, postoperative morbidity and

mortality is significantly increased and an alternative form of treatment for the hyperthyroidism is indicated.[93]

239.1.4.3 Radioactive Iodine

Administration of radioactive iodine as ^{131}I is considered to be the safest, simplest, and most effective therapy for feline hyperthyroidism. ^{131}I, like stable iodine, is actively concentrated by the thyroid gland, has a half-life of 8 days, and emits both β-particles and γ-radiation. The β-particles, cause over 80% of damage, but are locally destructive, traveling a maximum of 2 mm with an average path length of 400 μm. Therefore no significant damage occurs to adjacent parathyroid tissue, atrophic thyroid tissue, or other cervical structures. The aim of therapy is to restore euthyroidism with the smallest possible single dose of radiation, while avoiding the development of hypothyroidism or the persistence of hyperthyroidism.

Since its first use, controversy has surrounded the best method to calculate the optimum dose for individual cats. Tracer kinetic studies have been used that allow calculation of percentage iodine uptake, effective half-life, and estimation of thyroid gland weight—all factors known to influence the therapeutic dose.[98,99] The predictive value of tracer studies in estimating a therapeutic dose has been shown to be significantly closer to the therapeutic goal than the hypothetical administration of a fixed low dose (111 MBq).[100] However, this method requires access to sophisticated computerized nuclear medicine equipment, is time-consuming, expensive and can involve repeated sedation of the patient. It is therefore rarely used.

Another method is to use a relatively high fixed dose of between 148 and 250 MBq in all cats regardless of the size of the goiter or severity of the thyrotoxicosis.[101–105] Although this method is successful and simple, it potentially results in the under-or overtreatment of a significant proportion of cats. Extremely high fixed doses (> 1000 MBq) are retained for cats after surgical removal of a thyroid carcinoma.[106]

In most studies examining radioactive iodine therapy, it is recognized that markedly elevated pretreatment serum thyroid hormone concentration, the size of goiter, and the severity of the clinical thyrotoxicosis all potentially adversely affect the eventual response. The dose administered can be determined based on a scoring system that takes these factors into consideration.[107–109] When such a scoring system is used, doses range from 39 to 222 MBq, allowing titration to each individual cat and avoiding unnecessary under-or overtreatment. It is an extremely simple method that does not require access to sophisticated nuclear medicine equipment. Success is comparable to dose estimation by tracer kinetic studies.

Traditionally, ^{131}I is administered intravenously.[98,102–105,107–109] Oral administration has been attempted, but higher doses are generally required, the risks of radiation spillage are greater, and vomiting may occur.[101,104,110] Subcutaneous administration is equally effective, is simpler to administer, is safer to personnel, is less stressful to cats, and is currently preferred.[108,109,111] Whatever method of dose calculation or route of administration, attainment of euthyroidism is expected in over 90% of cats with a single dose (Figure 239-7). A small percentage of cats remain persistently hyperthyroid, but euthyroidism is eventually attained in some of these animals weeks to months later without further treatment.[108,109] Both hypothyroidism and recurrent hyperthyroidism can develop but appear to be rare, and other side effects are minimal.[112]

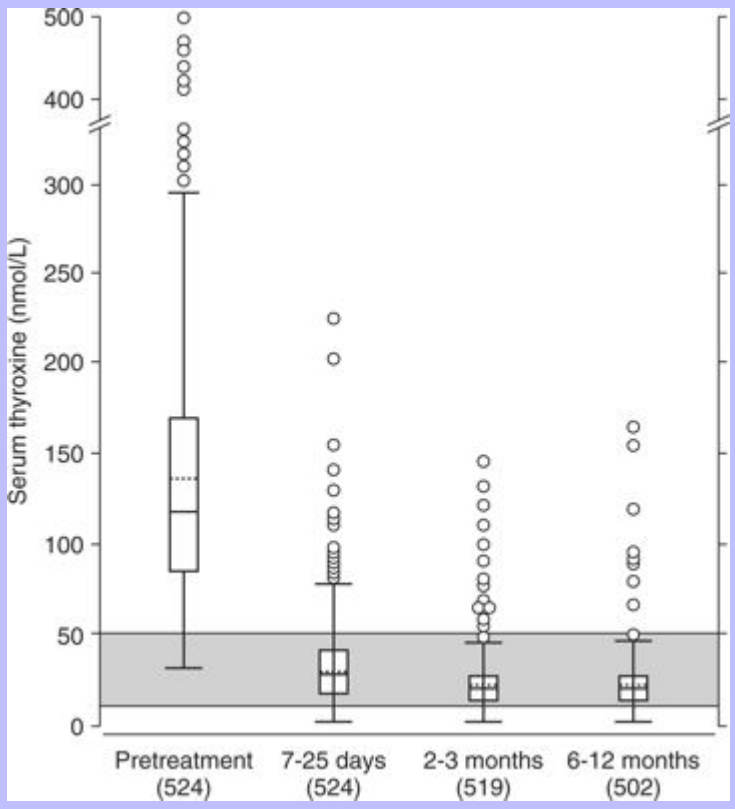
Several studies have estimated survival time in cats after treatment with hyperthyroidism. In one study of 66 cats followed for a mean of 13 months, 44 (67%) cats were alive and euthyroid 1 to 33 months after

treatment. The remaining cats had died of unrelated causes, including renal failure.[103] In a larger study of 524 cats, median survival time (MST) was 24 months (range 2 weeks to 7 years).[109] The percentage of cats alive at 1, 2, 3, and 4 years after treatment was 89%, 72%, 52%, and 34%, respectively. The most common causes of death in treated hyperthyroid cats are malignancy and renal disease.[109,113]

1557

1558

Figure 239-7 Box plots of serum total thyroxine (T_4) concentrations in 524 cats before and at various times after administration of radioiodine for treatment of hyperthyroidism. Data are plotted (i.e., box plots) as described in the legend of Figure 239-1. The shaded area indicates the reference range for serum T_4 concentration. To convert serum T_4 concentrations from nmol/L to ng/dL, divide the given values by 12.87. (From Peterson ME et al: Radioioidine treatment of 524 cats with hyperthyroidism. J Am Vet Med Assoc 207:1422, 1995.)



The effect of prior medical management on eventual outcome of radioactive iodine therapy is controversial. Obviously prior administration of stable iodine is contraindicated because of its inhibitory effect on the thyroid gland. Beta-blockers are often recommended because they have no effect on the thyroid gland *per*

se. However, prior methimazole (and therefore carbimazole) therapy has been suggested to enhance, worsen, or have no effect on radioiodine treatment outcome.[98,109,110,112] Methimazole does not inhibit thyroidal iodine uptake, but current administration adversely affects effective half-life of radioactive iodine and is not recommended.[100] However, iodine uptake is enhanced in healthy cats after recent methimazole withdrawal and this short-term rebound effect is potentially beneficial when treating with radioactive iodine.[78] A more recent study has shown that discontinuing methimazole for less than or greater than 5 days prior to radioactive iodine therapy has no effect on treatment outcome.[105]

The main drawback to widespread use of radioactive iodine is the requirement for special licensing and the isolation of the cat for variable periods after treatment. This can range from several days to several weeks, depending on the dose used and state or local radiation regulations.[1] Cats appear to tolerate these periods of hospitalization well.

239.1.4.4 Other Therapies

Intrathyroidal infusion of ethanol causes tissue necrosis and eventual induction of euthyroidism. Single injections in unilateral cases, preferably using ultrasound guidance, are efficacious in inducing euthyroidism in hyperthyroid cats.[114] Staged injections in bilateral cases are less successful in treating hyperthyroidism.[115] However, percutaneous ethanol injection is associated with a high incidence of adverse reactions such as transient dysphonia, Horner's syndrome, gagging, and laryngeal paralysis and cannot therefore be recommended for treatment of hyperthyroid cats.

Gene therapy could potentially be used to deliver cytotoxicity specifically to abnormally functioning thyroid cells. The feline thyroglobulin promoter has been characterized and its cell type specific activity demonstrated, paving the way for transcriptional targeting of gene therapy. However, a great deal of work is required before any such technology reaches veterinary practice.[116]

239.1.4.5 Effect of Treatment on Renal Function

Despite the potential adverse effect of hyperthyroidism on renal function, its presence can increase glomerular filtration rate (GFR), decrease serum creatinine concentration, and mask underlying renal disease.[34,55,117] Decreased GFR, increased serum urea and creatinine concentration, and development of overt clinical signs of renal disease have all been reported after successful treatment of hyperthyroidism, regardless of therapeutic modality utilized (methimazole, surgical thyroidectomy or radioiodine).[34,118–120] Assessment of GFR before treatment can act as a predictor of post-treatment renal failure with a low GFR in hyperthyroidism, indicating an increased risk for adverse clinical outcome.[119] However, techniques for assessment of GFR are impractical because they typically involve use of radioisotopes. Estimation of GFR is also possible using a plasma iohexol clearance test that requires no special licensing but is technically demanding.[120] In the absence of such estimations, accurate prediction of impending renal failure is difficult. However, serum urea and creatinine concentrations and USG should be carefully evaluated prior to treatment of hyperthyroidism. If both serum parameters are normal and the urine is concentrated, the risk of developing renal failure after therapy is minimized. Serum creatinine should be evaluated in light of the animal's muscle mass with lower values expected in emaciated cats.[34] If the serum creatinine and urea concentrations are higher than expected and the urine isosthenuric, a risk of developing renal failure exists. In such cases, trial therapy using either methimazole or carbimazole should be attempted and renal function

reassessed once euthyroidism is achieved. Initially low and then increasing doses of methimazole have been suggested in suspect cases, but limited scientific evidence exists to support this.[34] If no deterioration occurs after treatment of the hyperthyroidism, then a more permanent therapeutic option may be selected. If renal function declines, therapy should be instituted for renal failure and the dose of antithyroid medication adjusted to maximize renal function while attempting to control clinical signs. Maintenance of a mildly hyperthyroid state may be beneficial in some individuals. Avoidance of hypothyroidism is important because it may have its own detrimental effects on GFR.[34]

239.2 THYROID NEOPLASIA AND HYPERTHYROIDISM IN DOGS

Thyroid tumors account for 1.2% to 3.75% of all tumors and approximately 10% to 15% of all head and neck neoplasms in the dog. In pathologic studies, benign adenomas account for approximately 30% to 50% of all thyroid tumors, but these are usually small focal lesions uncommonly detected during life.[121,122] On the other hand, carcinomas, responsible for only 50 to 70% of all thyroid tumors diagnosed postmortem, account for up to 90% of those tumors detected antemortem. All thyroid masses detected during life should, therefore, be presumed malignant until proven otherwise. Carcinomas are usually larger than adenomas, coarsely multinodular, nonmobile, and often have necrotic or hemorrhagic centers or, occasionally, focal areas of mineralization or bone formation. Unilateral involvement is more than twice as common as bilateral involvement; when the latter occurs, the neoplastic process is usually extensive. It is therefore difficult to determine if the tumor arose in both thyroid lobes or if metastases occurred from one lobe to the other. Occasionally, ectopic thyroid tissue (arising from thyroglossal duct remnants) located anywhere from the base of the tongue to the base of the heart becomes neoplastic, and thyroid tumors must therefore be included in a range of differential diagnoses for oral, cervical, and thoracic masses.

Thyroid carcinomas are poorly encapsulated and commonly extend into or around the trachea, cervical muscles, esophagus, larynx, nerves, and blood vessels, although invasion into the esophageal or tracheal lumen is unusual. Metastatic spread to the retropharyngeal and cervical lymph nodes is common. However, early invasion into the cranial and caudal thyroid veins with the formation of tumor cell thrombi leads to multiple pulmonary metastases, often before involvement of regional lymph nodes. Other reported, but rare, sites of metastatic lesions include kidney, adrenal gland, liver, spleen, spinal cord, and bone.

Histopathologically, thyroid carcinomas are usually well differentiated and classified as follicular, compact (solid), mixed, or papillary. The majority of tumors in the dog are mixed, follicular, or less commonly, compact. The correlation between this histopathologic classification and ultimate prognosis is unclear. Undifferentiated (anaplastic) thyroid tumors appear to be highly malignant but are rare. Medullary (parafollicular, C-cell) carcinoma may have a more favorable prognosis, because distant metastatic spread is uncommon and they appear to be well encapsulated and easily resectable at the time of surgical thyroidectomy. However, specific immunocytochemical stains are required for diagnosis.[123] The probability of metastases clearly increases in proportion to the size of the tumor. Dogs with small thyroid tumors (< 20 cm^3) have a less than 20% incidence of metastatic disease, whereas nearly all dogs with large tumors (> 100 cm^3) have metastases.

1558
1559

239.2.1 Clinical Features

Thyroid tumors occur in middle-aged and older dogs, with an average age at onset of 10 years. Almost all dogs are greater than 4 years old at the time of diagnosis. No sex predilection exists, unlike the situation in humans in which females are more than twice as likely to develop thyroid cancer as males at most ages.

Beagles and golden retrievers appear predisposed to the development of thyroid carcinomas and boxers to the development of both adenomas and carcinomas.

Thyroid tumors are occasionally coincidentally found as freely mobile masses when grooming, petting, or during a general health check. However, most dogs have a visible mass in the neck or have its associated consequences (coughing, gagging, dysphonia, dysphagia, retching, regurgitation, and vomiting). The duration of these signs varies from weeks to months. The mass is usually felt in the region of the thyroid gland, below the larynx, but occasionally, larger tumors may descend toward the thoracic inlet. Clinical signs referable to regional (enlarged lymph nodes or cording of local lymphatic and blood vessels) or distant (dyspnea from pulmonary metastases) metastatic spread may be apparent. A few dogs may have the additional clinical signs of hypothyroidism or hyperthyroidism. Dogs with hyperthyroidism exhibit similar clinical signs to those in cats (weight loss, polyphagia, polyuria/polydipsia [PU/PD], restlessness, tachycardia) but tend to be less symptomatic.

In general, canine thyroid tumors are nonfunctional, and euthyroidism is maintained throughout the course of the disease. It has been suggested that up to 30% of dogs with detectable thyroid tumors are hypothyroid.[124] Hypothyroidism may arise because of destruction of all normal thyroid tissue by aggressive bilateral carcinomas. Alternatively, large tumors could potentially produce excessive inactive thyroid hormones capable of pituitary TSH suppression and eventual atrophy of normal thyroid tissue, although this has not yet been substantiated. A diagnosis of hypothyroidism must be approached with caution because of the suppressive effect of nonspecific illness on circulating thyroid hormone concentrations. Hyperthyroidism occurs in approximately 10% to 20% of thyroid carcinomas but is unusual in the rare cases of detectable adenomas.

In humans, thyroid tumors form part of the multiple endocrine neoplasia (MEN) syndromes in which neoplasia or hyperplasia develops in several different endocrine organs simultaneously. MEN syndromes are classified as type 1 or type 2, the latter further divided into type 2A and 2B. The MEN syndromes tend to involve one or more specific polypeptide-and biogenic amine-producing cell types, exhibit a histologic progression from hyperplasia to adenoma and (in some cases) to carcinoma, and each has an autosomal dominant pattern of inheritance. MEN type 1 syndrome involves parathyroid, pancreatic islet, and pituitary hyperplasia or neoplasia. MEN type 2A is associated with the development of bilateral pheochromocytomas, medullary thyroid carcinomas and, less commonly, parathyroid hyperplasia or adenoma. The association of medullary thyroid carcinoma and pheochromocytoma with multiple mucosal neuromas is termed *MEN type 2B*. Some patients do experience unusual manifestations of these syndromes, but these are less well characterized. Although rare, it has been suggested that MEN syndromes exist in dogs,[124] and a careful clinical evaluation should be carried out in all dogs with thyroid carcinoma.

239.2.2 Diagnosis

The differential diagnoses for large cervical swellings include abscess, granuloma, thyroid tumor, other tumors, and salivary mucocele. Fine needle (21 to 23 gauge) aspiration is helpful in distinguishing many of these. Unfortunately, because of the vascular nature of thyroid tissue, samples are frequently heavily contaminated with blood and exfoliation of neoplastic cells can be poor.[125] Evaluation of wide bore needle biopsies, although of greater diagnostic yield, significantly increases the risk of hemorrhage and should only be carried out under ultrasound guidance. Even with such biopsies there may still be difficulty in distinguishing benign from malignant tumors, and the latter is often only confirmed by demonstration of vascular or capsular invasion in biopsies taken at the time of surgical thyroidectomy.

Results of postmortem studies show that up to 80% of dogs have evidence of distant metastatic spread, although this decreases to just over 60% in clinical cases.[126] Thus it is imperative that once a mass is identified as thyroid, a systematic search for metastatic spread should follow. Routine screening laboratory tests may be helpful in identifying secondary organ involvement or concurrent problems that may ultimately affect the prognosis. Local lymph nodes should be carefully examined and biopsied as necessary. Radiography of the cervical area may help to assess the size of the mass and the extent of local invasion. Thoracic radiography should always be evaluated for evidence of pulmonary spread even in the absence of clinical signs. Abdominal radiography and ultrasonography may be useful in cases where hepatic metastasis is suspected.

As in cats, thyroid scintigraphy using radioactive iodine or technetium may be useful because most thyroid tumors and their metastases retain the ability to trap iodine. Such scans do not provide any information with regard to thyroid function but are helpful in depicting location of the tumor and regional metastases.[127] Some thyroid tumors fail to adequately concentrate radioisotopes, and it has been suggested that these are less likely to respond to radioactive iodine administration.[124] Compared with thoracic radiography, thoracic scintigraphy to depict pulmonary metastases is not considered useful.

Measurement of serum total T_4 concentration is necessary in dogs with appropriate clinical signs of thyrotoxicosis. Elevations are generally moderate, compared with the marked elevations often seen in hyperthyroid cats. Measurement of circulating endogenous TSH concentration is not useful due to the poor sensitivity of currently available assays and their inability to detect suppressed values. However, free T_4 in combination with cTSH measurements will provide the most useful information to support hypothyroidism if clinical signs are suggestive.

239.2.3 Treatment

Currently, several possible treatment options exist for thyroid carcinoma. Clinicians find that the selection of any one option is complicated by poorly defined prognostic indicators, inconsistencies in case selection and reporting criteria amongst the different studies, and the variety and number of treatments attempted in individual patients. However, it is clear that the prognosis is excellent for mobile, nonfixed tumors; that local control may halt metastatic spread; and that metastatic spread may not ultimately affect outcome with certain treatment options. In addition, functional state appears irrelevant and clinical signs of hyperthyroidism can easily be controlled using carbimazole or methimazole at 5 mg orally three times daily initially and subsequently adjusted for effect.

Surgical thyroidectomy is approached as for cats. However, in dogs most tumors are unilateral and therefore it is not necessary to preserve parathyroid glands on the affected side. In dogs with no evidence of metastatic spread and operable thyroid tumors, resection alone results in long-term control without subsequent development of metastases.[128] However, in many cases extensive local tumor invasion precludes complete removal, and aggressive surgical attempts significantly increase the risk of extensive hemorrhage and damage to the recurrent laryngeal nerves and parathyroid glands. In such cases, surgery alone is only associated with a 25% survival rate at 1 year.[123] Surgical debulking followed by chemotherapy with cisplatin or doxorubicin has been recommended for such cases.[129,130] Administration of radioactive iodine may be helpful if iodine uptake is maintained but generally high, and multiple doses must be used, limiting its value clinically.[124,131] Two recent studies suggest that definitive or palliative radiotherapy may be associated with the best survival.[132,133]

In these studies, prior existence of metastatic spread did not appear to alter survival, and there was a decreased risk of metastatic spread with local control of tumor progression.

Standard dose T_4 supplementation is necessary after bilateral thyroidectomy. In addition, T_4 therapy is usually recommended after unilateral thyroidectomy. Receptor affinity and concentration and functional response to TSH are similar in healthy and carcinomatous thyroids.[134] Although it is unclear if TSH has any growth-stimulating properties in thyroid neoplasia *in vivo*, T_4 therapy seems a wise precaution.

240 CHAPTER • 240 Insulin-Secreting Islet Cell Neoplasia

Rebecka S. Hess

Insulinoma is uncommon in the dog and rare in the cat. This chapter, therefore, focuses on canine insulinoma unless otherwise noted. The first case series documenting successful surgical therapy of insulinoma in human beings was reported by Whipple in 1935. *Whipple's triad* was defined as the presence of neurologic clinical signs associated with a low plasma glucose concentration and relieved by feeding or administration of glucose. Canine insulinoma was first described in 1935.[1]

240.1 PATHOLOGY

Insulin-secreting beta cell neoplasia is the most common islet cell neoplasia in the dog. This may be due to the fact that beta cells comprise approximately 70% of cells in the islets of Langerhans. Most canine insulinomas are malignant. In one immunocytochemical report, 17 of 18 insulinomas were carcinomas and only one was an adenoma.[2] About 80% of pancreatic tumors are solitary, and most are located in one of the two limbs of the pancreas rather than in the body.[3–5] Occasionally, no discrete nodule or nodules are apparent during gross examination of the pancreas, and histopathologic evaluation is needed to identify the tumor.

The rate of detected metastatic lesions in 179 dogs from different studies ranged from 45% to 64% and was higher in studies based on necropsy than in those based on surgical biopsies.[3,6,7] Clinical staging of pancreatic tumors according to the World Health Organization's tumor-node-metastasis (TNM) system defines stage I as $T_1N_0M_0$ (presence of a primary tumor and absence of regional lymph node or distant metastases), stage II as $T_1N_1M_0$, and stage III as $T_1N_1M_1$ or $T_1N_0M_1$. Most dogs with insulinoma have stage II or stage III disease.[8] The most common sites of metastases are regional lymph nodes and the liver. Other reported metastatic sites are the duodenum, mesentery, omentum, spleen, heart, and spinal cord.

Although the etiology of insulinoma is unknown, growth hormone production, which is not associated with increased plasma growth hormone concentrations, has been documented in primary and metastatic canine insulinoma lesions. Local growth hormone may affect insulinoma cell proliferation through paracrine or autocrine mechanisms.[9]

240.1.1 Pathophysiology

Proliferation of beta pancreatic cells results in excess secretion of insulin and therefore hypoglycemia. The most important compensatory mechanisms for hypoglycemia are inhibition of insulin secretion and stimulated secretion of counter-regulatory hormones.

Glucose is the primary regulator of insulin secretion. When glucose enters beta pancreatic cells, it is metabolized to adenosine triphosphate (ATP) and closes ATP-sensitive potassium (K^+) channels. Closure of the K^+ channels reduces K^+ efflux and results in depolarization of the beta cell and opening of voltage-sensitive calcium (Ca^{2+}) channels. An increase in the cytoplasmic Ca^{2+} concentration results in insulin exocytosis. In a normal animal, insulin secretion is completely inhibited when the blood glucose concentration is less than 65 to 80 mg/dL. However, insulin secretion from neoplastic beta cells occurs independent of the blood glucose concentration and persists despite a low blood glucose concentration.

Therefore the hallmark of an insulin-secreting tumor (insulinoma) is an increased blood insulin concentration despite a low blood glucose concentration.

The four counter-regulatory hormones secreted in response to hypoglycemia are glucagon, catecholamines, growth hormone, and glucocorticoids. Of these hormones, glucagon and catecholamines are most important in increasing the blood glucose concentration.

240.2 HISTORY AND CLINICAL SIGNS

The mean age of dogs with insulinoma is 9 years (range, 3 to 15 years). Although any breed can develop an insulinoma, the tumor has been reported mainly in medium to large breed dogs. Controlled studies of breed risk for insulinoma have not been published, and there is no apparent sex predilection for the disease.

Most clinical signs arise from the effect of hypoglycemia on the central nervous system (neuroglycopenia) or from hypoglycemia-induced release of catecholamines. Glucose is the single most important source of energy in the brain, and carbohydrate storage in neural tissue is limited. Brain function, therefore, depends on a continuous supply of glucose. Clinical signs attributable to neuroglycopenia include seizures, collapse, weakness, ataxia, disorientation, mental dullness, and visual disturbances. Clinical signs related to excess catecholamine release and stimulation of the sympathetic nervous system include tremors, hunger, and nervousness.

The severity of clinical signs increases as blood glucose drops, and severe hypoglycemia ultimately can result in coma and death. Clinical signs may also be related to the duration of the hypoglycemia and the rate at which it develops, because a gradual decrease in the blood glucose concentration may be less likely to stimulate catecholamine secretion. Occasionally clinical signs are episodic, because secretion of counter-regulatory hormones elevates the blood glucose concentration and temporarily resolves neuroglycopenic clinical signs. Feeding can result in either alleviation or exacerbation of clinical signs. If feeding restores the blood glucose concentration to normal, the clinical signs resolve. However, feeding may also stimulate insulin secretion and exacerbate the clinical signs. Fasting, exercise, or excitement can worsen clinical signs either by decreasing the blood glucose concentration or by increasing sympathetic stimulation.

Clinical signs reported in 198 dogs from several studies are listed in Table 240-1.[3–5,7,8,10] Although most dogs have more than one of these clinical signs, some dogs have none. The reported duration of clinical signs prior to diagnosis varies from 1 day to 3 years.

240.2.1 Physical Examination

The physical examination is unremarkable in most dogs with insulinoma.[4,6] Dogs may be overweight as a result of the anabolic effects of insulin, and postictal findings may be apparent if the dog has had a recent seizure. A peripheral polyneuropathy, characterized by tetraparesis and decreased or absent appendicular reflexes, has been described in association with insulinoma in 13 dogs.[8,11,12] The etiology of insulinoma-associated peripheral neuropathy is not known. It has been suggested that this polyneuropathy develops as a paraneoplastic immune-mediated disorder that is unrelated to the metabolic changes associated with insulinoma.[12]

240.3 DIFFERENTIAL DIAGNOSES

Differential diagnoses for hypoglycemia may be categorized as (1) those associated with excess secretion of insulin or insulin-like factors, (2) those associated with decreased glucose production, (3) those associated with excess glucose consumption, (4) drug-associated causes, and (5) spurious causes. Disorders in which the most important mechanism for hypoglycemia is excess secretion of insulin or insulin-like factors include insulinoma, extrapancreatic tumor, and islet cell hyperplasia. Conditions associated with decreased glucose production include hypoadrenocorticism, hypopituitarism, growth hormone deficiency, liver diseases, glycogen storage diseases, neonates, and toy breeds. Fasting, malnutrition, and pregnancy may also result in hypoglycemia. Excess glucose consumption may develop in sepsis or extreme exercise. Some of the many drugs reported to induce hypoglycemia in human beings include insulin, oral hypoglycemics (e.g., sulfonylurea), salicylates (e.g., aspirin), acetaminophen, beta blockers (e.g., propranolol), $beta_2$-agonists, ethanol, monoamine oxidase inhibitors, tricyclic antidepressants (e.g., amitriptyline), angiotensin-converting enzyme inhibitors (e.g., captopril), antibiotics (e.g., tetracycline), lidocaine overdose, and lithium. Factitious hypoglycemia may occur when blood cells are not promptly separated from serum or in cases of severe polycythemia or leukocytosis if serum separation is delayed longer than 1 hour.

Table • 240-1 Clinical Signs Reported in 198 Dogs from Several Studies[3–5,7,8,10]

CLINICAL SIGN	NUMBER OF DOGS
Seizure	95
Collapse	79
Generalized weakness	74
Shaking/trembling/muscle twitching	40
Ataxia	40
Exercise intolerance	30
Hindlimb weakness	28
Disorientation/bizarre behavior/hysteria	19
Polyphagia	16
Polyuria and polydipsia	16
Stupor/lethargy	12
Focal facial seizures	6
Obesity or weight gain	6
Blindness	5
Anorexia	5
Diarrhea	4
Head tilt	2
Nervousness	2

240.3.1 Diagnostic Evaluation

A clinical suspicion of insulinoma is established with documentation of appropriate clinical signs, hypoglycemia (blood glucose concentration less than 60 mg/dL), and concurrent hyperinsulinoma (serum insulin concentration greater than 20 μU/mL).[13] Identification of a pancreatic mass with imaging studies may strengthen this suspicion. The diagnosis of insulinoma is confirmed with histologic examination and immunohistochemical staining of the pancreatic mass.

The results of a complete blood count, chemistry screen, and urinalysis are usually unremarkable, aside from the low blood glucose concentration.[4,7] Although hypoglycemia is observed in most dogs with insulinoma, especially if the measurement is repeated twice,[7] it is important to remember that some dogs with insulinoma may have euglycemia on repeated measurements.[14] Mild hypokalemia and increased serum alkaline phosphatase or alanine aminotransferase activities have also been documented.[5,7]

If a dog suspected of having an insulinoma has euglycemia, it should be fasted and the blood glucose concentration should be measured every 1 to 2 hours. In most dogs with insulinoma, hypoglycemia develops within 12 hours of fasting. Blood for measurement of the insulin concentration should be collected when the animal is hypoglycemic, and it should then be fed. However, a small percentage of dogs do not exhibit hypoglycemia, even with repeated measurements and after a prolonged fast (48 to 72 hours).[7] A low fructosamine concentration has been used to strengthen the clinical suspicion of insulinoma in several dogs with euglycemia.[14] The glycosylated hemoglobin A1c concentration has been significantly low in some but not all dogs with insulinoma.[15] Repetition of serum insulin measurements may also aid in the diagnosis. One study of canine insulinoma found that 76% of dogs had an increased serum insulin concentration when it was measured once, and 91% of dogs had an increased serum insulin concentration when it was measured twice.[7]

1561

1562

Other tests have been described as aids in the diagnosis of insulinoma in euglycemic dogs with a normal serum insulin concentration. However, insulin to glucose and glucose to insulin ratios are not recommended because of their low sensitivity, and the amended insulin to glucose ratio is not recommended because of its low specificity. Additional tolerance and stimulation tests have been described but are not advocated because of questionable usefulness and potentially fatal side effects, such as hypoglycemia and seizures.[16]

Most dogs with insulinoma have normal abdominal and thoracic radiographs.[4,6,8,17] According to the combined results of several studies in which abdominal ultrasound scans were performed in dogs with insulinoma, a pancreatic mass was identified in 49 of 87 (56%) dogs, and abdominal metastasis was noted in 17 of 87 (20%).[3,5,8,17] Although abdominal ultrasonography may be helpful in increasing the clinical suspicion of a pancreatic mass and metastases, both false-positive and false-negative results have been described.

Computed tomography (CT) is the most common imaging technique used for identification of pancreatic tumors in human beings; it detects about 50% of tumors greater than 2 cm in diameter and almost none of the smaller tumors.[18] CT has been reported in a small number of dogs with insulinoma, but its sensitivity in dogs has yet to be determined.[8] Intravenous administration of radioactively labeled synthetic somatostatin, followed by whole body scintigraphy, has been shown to be a sensitive and specific tool for pancreatic tumor imaging in humans[18] and has been reported in one dog with insulinoma.[19] Intravenous intraoperative administration of methylene blue was used to characterize pancreatic tumors in five dogs.[20]

240.4 TREATMENT

Therapy for insulinoma can be divided into treatment of the acute hypoglycemic crisis and long-term management. During an acute hypoglycemic crisis, dextrose can be given as a slow bolus (0.5 g/kg given intravenously, diluted in 0.9% sodium chloride at a 1:3 ratio). The bolus is followed by an intravenous continuous-rate infusion of dextrose (2.5% to 5% in water). Dextrose must be administered with caution because

it can stimulate insulin secretion and cause hypoglycemia. Fluid resuscitation is performed as necessary. In most dogs, neuroglycopenia resolves with administration of dextrose. However, if the animal fails to respond to dextrose administration alone, dexamethasone (0.5 mg/kg given intravenously over 6 hours, every 12 to 24 hours) and a somatostatin analog (20 to 40 μg given subcutaneously every 8 to 12 hours) may be administered. In severe cases the animal may have to be sedated with pentobarbital for several hours while the above treatment is continued and until seizures resolve.[21]

A continuous-rate infusion of glucagon (5 to 13 ng/kg/min with or without a concurrent 10% dextrose infusion) has been reported in one dog with insulinoma-associated hypoglycemia. Clinical signs attributed to the hypoglycemia resolved within 20 minutes, and the hypoglycemia resolved within 1 hour. Glucagon increases the blood glucose concentration by promoting glycogenolysis and gluconeogenesis. However, glucagon also increases insulin secretion, and animals should be monitored carefully for worsening hypoglycemia.[22]

The long-term treatment of choice for insulinoma is surgical resection of the tumor and gross metastases.[5] Surgical exploration and biopsy of the pancreatic mass also can confirm the diagnosis and may aid estimation of the survival time.[10] When postoperative hyperglycemia develops, it usually is transient and resolves once normal beta cells, which have been suppressed by excess insulin secretion from neoplastic cells, regain their function. However, about 10% of dogs develop diabetes mellitus and require treatment with exogenous insulin for 1 to 37 months.[6,7,10] Other postoperative complications include acute pancreatitis, diabetic ketoacidosis, delayed wound healing, ventricular arrhythmias and cardiac arrest, hemorrhage, sepsis, and leukopenia.[3,5,7]

The discussion of medical therapy is limited to clinically important agents reported as having been used in dogs with spontaneous insulinoma. The use of additional medications is discussed elsewhere.[21] Medical treatment is indicated prior to surgery, postoperatively if needed, and in cases in which surgery is not performed. Medical therapy can be divided into cytotoxic treatment directed at destroying insulin-secreting beta cells and treatment aimed at relieving the hypoglycemia.

Streptozocin is a nitrosourea antibiotic derived from the bacterium *Streptomyces achromogenes*. Streptozocin selectively destroys beta cells in the pancreas or metastatic sites. The drug is nephrotoxic and has been reported to cause acute renal failure and renal tubular atrophy in the dog. Diuresis with saline decreases the drug's contact time with renal tubular epithelial cells and may reduce the risk of nephrotoxicity. Successful use of streptozocin in veterinary medicine is limited to a study of 17 dogs, most of which had surgery with incomplete resection of gross lesions.[8] Dogs were treated with 0.9% sodium chloride (18 mL/kg/hr given intravenously) for 3 hours prior to streptozocin administration, during 2 more hours of streptozocin treatment, and for 2 additional hours after treatment. Streptozocin (500 mg/m^2) was given every 3 weeks. Butorphanol (0.4 mg/kg given intramuscularly) was administered immediately after streptozocin therapy as an antiemetic, but vomiting still occurred in about 30% of treatments. Other side effects included diabetes mellitus, transient hypoglycemia and seizures, transient hyperglycemia, transient increases in alanine aminotransferase activity, azotemia, mild thrombocytopenia, and mild neutropenia. The median duration of normoglycemia in dogs treated with streptozocin was 163 days, which was not significantly different from the median duration in control dogs treated surgically or medically. Further studies are needed to determine whether the benefits of streptozocin treatment outweigh its risks.

The main methods of relieving hypoglycemia include dietary modification and treatment with prednisone, diazoxide, or synthetic somatostatin. Small, frequent meals (every 4 to 6 hours) of a diet high in protein, fat, and complex carbohydrates are recommended, and simple sugars (present in soft, moist dog foods) should be avoided.

Prednisone increases the blood glucose concentration by increasing gluconeogenesis and glucose 6-phosphatase activity, decreasing blood glucose uptake into tissue, and stimulating glucagon secretion. Glucocorticoids can be administered intravenously in the form of dexamethasone during an acute hypoglycemic crisis or can be given orally once the dog is stable. Prednisone, the least expensive and most commonly used drug for the treatment of canine insulinoma, should be administered at a dosage of 0.5 to 4 mg/kg/day given orally, beginning with the lower end of the dosage and gradually increasing if necessary.[10,21]

1562

1563

Diazoxide is a benzothiadiazine derivative, the main action of which is to inhibit closure of ATP-dependent K^+ channels in beta pancreatic cells. This prevents depolarization of beta cells and inhibits opening of voltage-dependent Ca^{2+} channels. Decreased Ca^{2+} influx results in decreased exocytosis of insulin-containing secretory vesicles. Diazoxide also increases the blood glucose concentration in pancreatized dogs by increasing glycogenolysis and gluconeogenesis and by inhibiting tissue uptake of glucose.[23] Diazoxide is administered at a dosage of 10 to 40 mg/kg/day given orally, divided every 8 to 12 hours, beginning at the lower end of the dosage and gradually increasing if needed. Approximately 70% of dogs with insulinoma respond to treatment with diazoxide.[7] Side effects in dogs, which are uncommon, include ptyalism, vomiting, and anorexia. However, in human beings, myocardial ischemia, salt retention, water retention, hyperglycemia, hypotension, and cerebral ischemia have also been reported.

Octreotide is a long-acting synthetic somatostatin analog, and its main mode of action is inhibition of insulin secretion. In human beings, octreotide's action depends on its binding affinity to any of five somatostatin receptor subtypes present in tumors. Dogs have only one somatostatin receptor subtype, and their response to octreotide is variable.[24] The lack of a dependable response to octreotide in dogs may be due to the drug's inhibition of glucagon and growth hormone secretion. If suppression of glucagon and growth hormone secretion is of greater magnitude and duration compared with suppression of insulin secretion, octreotide may actually worsen the hypoglycemia. Also, some canine insulinomas may not have somatostatin receptors. For these reasons, further studies are needed to determine octreotide's efficacy and safety in dogs. Octreotide has been administered to dogs with insulinoma at dosages of 2 to 4 µg/kg given subcutaneously every 8 to 12 hours.[25] Side effects have not been reported in dogs; in humans they are mild and include pain at the site of injection (which can be reduced if octreotide is warmed to room temperature before administration), nausea, vomiting, abdominal pain, constipation, and steatorrhea.

240.5 PROGNOSIS

The median survival time of 142 dogs that underwent partial pancreactomy, as reported in several studies, was 12 to 14 months, with a range of zero days to 5 years.[3–5,7,10] Several prognostic factors have been identified. Dogs with clinical stage I disease have a significantly longer disease-free interval, and about 50% are expected to be normoglycemic 14 months after surgery compared with only 20% of dogs with clinical stage II or stage III disease.[6] Young dogs have a worse prognosis.[6] Dogs with postoperative hyperglycemia or normoglycemia have a significantly better prognosis than those with hypoglycemia.[3]

A decreased mitotic rate is strongly associated with survival of human beings with insulinoma. Although a correlation between the number of mitotic figures per high-power field and local invasiveness of the tumor has been documented in dogs, a significantly worse prognosis in dogs with a high mitotic count has yet to be established.[10]

Age, sex, body weight, clinical signs and their duration, ultrasonographic detection of a pancreatic mass, tumor location, gross presence of metastatic disease, and the blood glucose or insulin concentration are not significantly associated with the prognosis.

240.6 INSULIN-SECRETING ISLET CELL NEOPLASIA IN THE CAT

Feline insulinoma is rare; it has been reported in five cats that were 12 to 17 years of age. Three of the cats were Siamese, and four were neutered males. The history and clinical signs are similar to those reported for dogs with insulinoma. The diagnosis is based on documentation of an increased serum insulin concentration at the time of hypoglycemia. Care must be taken to use an insulin radioimmunoassay validated for cats. Therapy consists of surgical resection of the pancreatic mass and metastases, followed by prednisone treatment and small frequent meals.[21,26]

241 CHAPTER • 241 Diabetes Mellitus

Richard W. Nelson

The endocrine pancreas is composed of the islets of Langerhans, which are dispersed as “small islands” in a “sea” of exocrine-secreting acinar cells. Four distinct cell types have been identified in these islets on the basis of staining properties and morphology: *alpha cells,* which secrete glucagon; *beta cells,* which secrete insulin; *delta cells,* which secrete somatostatin; and *F cells,* which secrete pancreatic polypeptide. Dysfunction involving any of these cell lines ultimately results in either an excess or a deficiency of the respective hormone in the circulation. In the dog and cat, the most common disorder of the endocrine pancreas is diabetes mellitus, which results from an absolute or relative insulin deficiency due to deficient insulin secretion by the beta cells. The incidence of diabetes mellitus is similar for the dog and cat, with the reported frequency varying from 1 in 100 to 1 in 500.[1]

241.1 CLASSIFICATION AND ETIOLOGY

241.1.1 Overview of Classification

In humans, diabetes mellitus is classified as type 1 or type 2 based on the pathophysiologic mechanisms and the pathogenic alterations affecting the beta cells. Type 1 diabetes is characterized by a combination of genetic susceptibility and immunologic destruction of beta cells, with progressive and eventually complete insulin insufficiency. The presence of circulating autoantibodies against insulin, the beta cell, and/or glutamic acid decarboxylase (GAD) usually precedes the development of hyperglycemia or clinical signs. Type 2 diabetes mellitus is characterized by insulin resistance and “dysfunctional” beta cells; defects believed to be genetic in origin are evident for a decade or longer before hyperglycemia and clinical signs of diabetes develop, and the deleterious effects can be accentuated by environmental factors such as obesity.[2,3] Humans with type 1 diabetes are dependent on insulin for control of the disease (i.e., insulin-dependent diabetes mellitus [IDDM]), whereas control of the diabetic state in humans with type 2 diabetes is usually possible through diet, exercise, and oral hypoglycemic drugs. Insulin treatment may be necessary in some type 2 diabetics if insulin resistance and beta cell dysfunction are severe. As such, humans with type 2 diabetes can have IDDM or non-insulin-dependent diabetes mellitus (NIDDM).

It is more clinically relevant and perhaps more accurate to classify diabetes in dogs and cats as IDDM or NIDDM rather than as type 1 or type 2. The familial history is rarely available in diabetic dogs and cats, and the clinical presentation is usually not helpful in differentiating type 1 and type 2 diabetes, especially in cats. Insulin secretagogue tests are not routinely performed, and their results may be misleading. Autoantibody tests for type 1 diabetes are not readily available.[4,5] Therefore, as clinicians, veterinarians usually classify diabetic dogs and cats as either IDDM or NIDDM based on their need for insulin treatment. This can be confusing, because some diabetics, especially cats, initially can appear to have NIDDM progressing to IDDM, or they flip back and forth between IDDM and NIDDM as the severity of insulin resistance and the impairment of beta cell function waxes and wanes. Apparent changes in the diabetic state (i.e., IDDM and NIDDM) are understandable when one realizes that islet pathology may be mild to severe and progressive or static; that the ability of the pancreas to secrete insulin depends on the severity of islet pathology and can decrease with time; that the responsiveness of tissues to insulin varies, often in conjunction with the presence or absence of concurrent inflammatory, infectious, neoplastic, or hormonal disorders; and that all these variables affect the animal's need for insulin, the insulin dosage, and the ease of diabetic regulation.

241.1.2

Insulin-Dependent Diabetes Mellitus

The most common clinically recognized form of diabetes mellitus in the dog and cat is IDDM. In our hospital, virtually all dogs and 50% to 70% of cats have IDDM at the time diabetes mellitus is diagnosed. Insulin-dependent diabetes mellitus is characterized by permanent hypoinsulinemia and an absolute necessity for exogenous insulin to maintain glycemic control. The etiology of IDDM has been poorly characterized in dogs and cats but is undoubtedly multifactorial (Box 241-1).

In the dog, genetic predispositions have been suggested by familial associations (Table 241-1).[6,7] Common histologic abnormalities in dogs include a reduction in the number and size of pancreatic islets, a decrease in the number of beta cells within islets, and beta cell vacuolation and degeneration (Figure 241-1). In some dogs an extreme form of the disease may occur, represented by a congenital absolute deficiency of beta cells and pancreatic islet hypoplasia or aplasia. Less severe changes of pancreatic islets and beta cells may predispose the adult dog to diabetes mellitus after it has been exposed to environmental factors, such as insulin-antagonistic diseases and drugs, obesity, and pancreatitis. Environmental factors may induce beta cell degeneration secondary to chronic insulin resistance or may cause release of beta cell proteins that induce immune-mediated destruction of the islets.[8] The results of studies evaluating for anti–beta cell autoantibodies in diabetic dogs have been conflicting; the autoantibodies were identified in newly diagnosed diabetic dogs with IDDM in one study[9] but not in another.[10] Immune-mediated insulitis has also been described in diabetic dogs.[11] Seemingly, autoimmune mechanisms, in conjunction with genetic and environmental factors, may play a role in the initiation and progression of diabetes in dogs.

Common histologic abnormalities in cats with IDDM include islet-specific amyloidosis (see Noninsulin-Dependent Diabetes Mellitus), beta cell vacuolation and degeneration, and chronic pancreatitis (see Figure 241-1).[12] The cause of beta cell degeneration is not known. Still other diabetic cats have a reduction in the number of pancreatic islets and/or insulin-containing beta cells on immunohistochemical evaluation, a finding that suggests that additional mechanisms may be involved in the physiopathology of diabetes mellitus in cats. Although lymphocytic infiltration of islets, in conjunction with islet amyloidosis and vacuolation, has been described in two diabetic cats,[13] this histologic finding is uncommon, and beta cell and insulin autoantibodies have not been identified in newly diagnosed diabetic cats.[14] The role of genetics remains to be determined.

From Guptill L et al: Is canine diabetes on the increase? *In* Recent Advances in Clinical Management of Diabetes Mellitus, Iams, Dayton, Ohio, 1999, p 24.

* Derived from analysis of the Veterinary Medical Database (VMDB) from 1970 to 1993. The VMDB comprises medical records of 24 veterinary schools in the United States and Canada. VMDB case records analyzed included those from first hospital visits of 6078 dogs with a diagnosis of diabetes mellitus and 5922 randomly selected dogs with first hospital visits for any diagnosis other than diabetes mellitus seen at the same veterinary schools in the same year. Only breeds with more than 25 cases of diabetes mellitus are included.

241.1.3 Noninsulin-Dependent Diabetes Mellitus

Clinical recognition of NIDDM occurs more often in the cat than in the dog, accounting for approximately 30% of diabetic cats seen at our hospital. Clinical recognition of NIDDM is uncommon in the dog and is usually associated with a concurrent insulin-antagonistic disease or drug. In humans, obesity, genetics, and islet amyloidosis are important factors in the development of NIDDM. Amyloid is a common pathologic finding in the pancreatic islets of diabetic cats. Islet amyloid polypeptide (IAPP), or amylin, is the principal constituent of amyloid isolated from the pancreatic tissue of humans with NIDDM and of adult cats with diabetes.[15] The amino acid sequence of human and feline IAPP is similar[16]; immunoelectron microscope

studies have identified IAPP in beta cell secretory granules in both cats and humans,[17,18] and amylin is cosecreted with insulin by the beta cell.[19] Stimulants of insulin secretion also stimulate the secretion of amylin. Amylin acts as a neuroendocrine hormone, having several glucoregulatory effects that collectively complement the actions of insulin in postprandial glucose control. These effects include a slowing of the rate at which nutrients are delivered from the stomach to the small intestine for absorption, suppression of nutrient-stimulated secretion of glucagon, and stimulation of satiety.[20,21] Chronic increased secretion of insulin and amylin, as occurs with obesity and other insulin-resistant states, results in aggregation and deposition of amylin in the islets as amyloid (see Figure 241-1). IAPP-derived amyloid fibrils are cytotoxic and are associated with apoptotic cell death of islet cells and a resultant defect in insulin secretion.[22–24] If deposition of amyloid is progressive, islet cell destruction progresses and eventually leads to diabetes mellitus (Figure 241-2). The severity of islet amyloidosis would determine in part whether the diabetic cat has IDDM or NIDDM (Figure 241-3). Total destruction of the islets results in IDDM and the need for insulin treatment for the rest of the cat's life. Partial destruction of the islets may or may not result in clinically evident diabetes, insulin treatment may or may not be required to control glycemia, and transient diabetes may or may not develop once treatment is initiated. If amyloid deposition is progressive, the cat progresses from a subclinical diabetic state to NIDDM and ultimately to IDDM.

The presence and severity of insulin resistance is an important variable that influences the clinical picture in cats with partial destruction of pancreatic islets. Insulin resistance increases the demand for insulin secretion, a demand that may not be met in some cats with partial destruction of islets. The more severe the insulin resistance and the loss of islets, the greater the likelihood that hyperglycemia will develop. Persistent hyperglycemia can in turn suppress function of remaining beta cells, causing hypoinsulinemia and worsening hyperglycemia (see Transient Diabetes Mellitus). A sustained demand for insulin secretion in response to insulin resistance can also lead to worsening islet pathology and a further reduction in the population of beta cells. Any chronic insulin-resistant disorder can have a deleterious impact on the population and function of beta cells and can play a role in the development of NIDDM or IDDM. Examples in the cat include obesity, chronic pancreatitis, acromegaly, hyperadrenocorticism, and chronic administration of glucocorticoids or megestrol acetate. Obesity-induced carbohydrate intolerance is the classic insulin-resistant disorder affiliated with the development of NIDDM in humans and has been identified as a potential causative factor in the development of diabetes in cats as well.[1,25] Obesity causes a reversible insulin resistance that is a result of downregulation of insulin receptors, impaired receptor binding affinity for insulin, and postreceptor defects in insulin action. Impaired glucose tolerance and an abnormal insulin secretory response have been documented in obese cats,[26,27] abnormalities that are reversible with correction of obesity.[28,29]

Our current understanding of the etiopathogenesis of diabetes in the cat suggests that the difference between IDDM and NIDDM is primarily a difference in the severity of loss of beta cells and the severity and reversibility of concurrent insulin resistance. Most cats with IDDM or NIDDM have islet amyloidosis, vacuolar degeneration of beta cells, or islet hypoplasia.[12,30] The more severe the islet pathology, the more likely the cat is to have IDDM, regardless of concurrent insulin resistance (see Figure 241-3). The less severe the islet pathology, the greater the role of concurrent insulin resistance in determining whether the cat has IDDM or NIDDM. The more severe and the less reversible the cause of the insulin resistance, the more likely the cat with mild islet pathology is to be insulin dependent, and vice versa. Fluctuations in the severity of insulin resistance, as occur with chronic pancreatitis, can cause a cat with mild islet pathology to oscillate between IDDM and NIDDM as the severity of pancreatic inflammation waxes and wanes. Persistent insulin resistance can also worsen islet pathology and cause the diabetic cat to progress from NIDDM to IDDM as the progressive loss of beta cells leads to worsening insulin deficiency.[30,31]

Figure 241-1 Pancreatic islet cell histology. **A,** Severe islet amyloidosis from a cat with insulin-dependent diabetes mellitus (IDDM) (hematoxylin and eosin stain [H&E], ×100). **B,** Severe islet cell degeneration and vacuolation from a cat with IDDM (H&E, ×200). (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 2nd ed. Philadelphia, WB Saunders, 1996, p 341.)

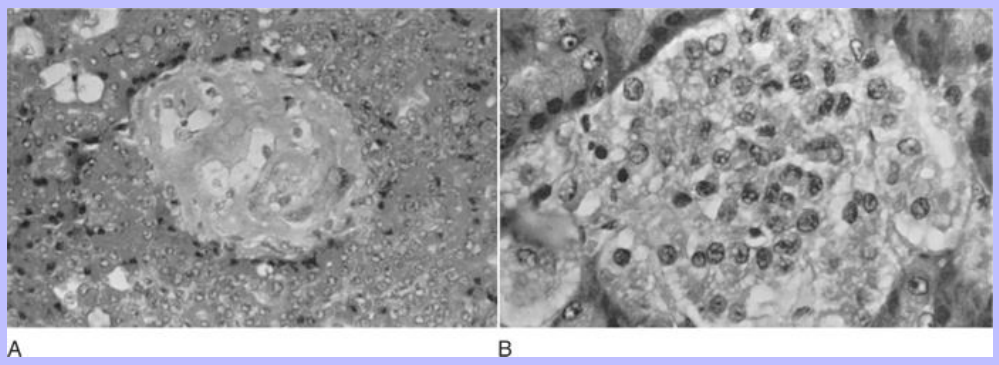

Figure 241-2 Schematic of the interplay between insulin resistance, amylin secretion, and amyloid deposition in the pancreatic islets. Insulin secretion increases to compensate for insulin resistance induced by environmental factors, insulin-antagonistic drugs, and concurrent illness. Because amylin and insulin are cosecreted, amylin secretion also increases in insulin-resistant states. If sustained, increased amylin secretion can lead to amylin aggregation and the formation of amyloid in the islets. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders, 2004.)

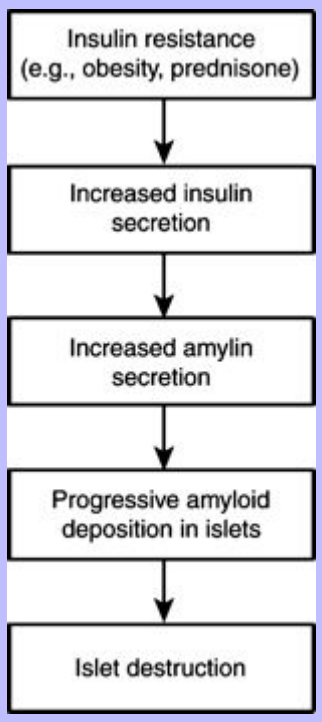


241.1.4 Transient Diabetes Mellitus

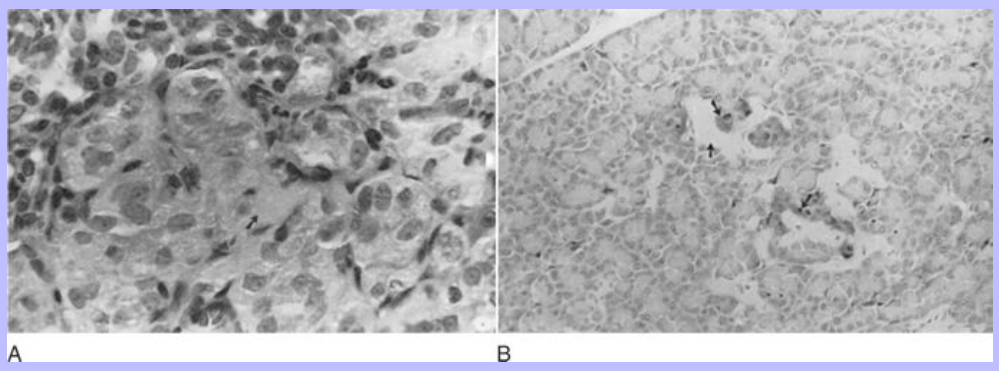
Approximately 20% of diabetic cats become “transiently diabetic,” usually within 4 to 6 weeks of establishment of the diagnosis of diabetes and initiation of treatment. In these cats, hyperglycemia, glycosuria, and clinical signs of diabetes resolve, and insulin treatment can be discontinued. Some diabetic cats may never require insulin treatment once the initial bout of clinical diabetes mellitus has dissipated, whereas others become permanently insulin dependent weeks to months after resolution of a prior diabetic state. Based on findings from a recent evaluation of a group of cats with transient diabetes mellitus, the author theorizes that cats with transient diabetes are in a subclinical diabetic state that becomes clinical when the pancreas is stressed by exposure to a concurrent insulin-antagonistic drug or disease, most notably glucocorticoids,

megestrol acetate, or chronic pancreatitis (Figure 241-4).[30] Unlike healthy cats, those with transient diabetes mellitus have some abnormality of the islets (e.g., amyloidosis, vacuolar degeneration) and a significant reduction in the population of beta cells. Islet abnormalities impair the ability to compensate for concurrent insulin resistance, resulting in carbohydrate intolerance. Insulin secretion by beta cells becomes reversibly suppressed, most likely as a result of worsening carbohydrate intolerance. Chronic hyperglycemia impairs insulin secretion by beta cells and induces peripheral insulin resistance by promoting the downregulation of glucose transport systems and causing a defect in post-transport insulin action; this phenomenon is referred to as *glucose toxicity*.[32] Beta cells have an impaired response to stimulation by insulin secretagogues, thereby mimicking IDDM. The effects of glucose toxicity are potentially reversible upon correction of the hyperglycemic state. The clinician makes a correct diagnosis of diabetes and initiates appropriate treatment for diabetes and identifiable insulin-antagonistic disorders. Treatment improves hyperglycemia and insulin resistance, the suppressive effects of hyperglycemia decrease, beta cell function improves, insulin secretion returns, and an apparent IDDM state resolves. The future requirement for insulin treatment depends on the underlying abnormality in the islets. If the islet pathology is progressive (e.g., amyloidosis), eventually enough beta cells are destroyed to cause permanent IDDM.

1566

1567

Figure 241-3 Pancreatic amyloidosis. **A,** Mild islet amyloidosis *(arrow)* and vacuolar degeneration in a cat with non-insulin-dependent diabetes mellitus (NIDDM) treated with diet and glipizide (H&E, ×200). **B,** Severe islet amyloidosis *(straight arrow)* in a cat with initial NIDDM that progressed to IDDM. Pancreatic biopsy was obtained during IDDM state. Residual beta cells containing insulin *(curved arrows)* are also present. (Immunoperoxidase stain, ×100). (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders, 2004, p 542.)



Transient or reversible diabetes is extremely uncommon in dogs and usually occurs in dogs with subclinical diabetes treated with insulin-antagonistic drugs (e.g., glucocorticoids) or in the early stages of an insulin-antagonistic disorder (e.g., diestrus in the bitch, hyperadrenocorticism). Such dogs have a reduced but adequate mass of functional beta cells to maintain carbohydrate tolerance when insulin resistance is not present but are unable to secrete an adequate amount of insulin to maintain euglycemia in the presence of insulin antagonism. Early recognition and correction of the insulin antagonism may re-establish euglycemia

without the long-term need for insulin therapy. Failure to correct the insulin antagonism quickly results in progressive loss of beta cells and the eventual development of IDDM.

241.1.5 Diagnosis of Insulin-Dependent versus Noninsulin-Dependent Diabetes Mellitus

Dogs and cats are not usually brought to a veterinarian until clinical signs of diabetes become obvious and worrisome to an owner. As such, at the time of diagnosis, all diabetic dogs and cats have fasting hyperglycemia and glycosuria, regardless of the type of diabetes mellitus that may be present. Once the diagnosis of diabetes has been established, the clinician must consider the possibility of NIDDM and the need for insulin treatment. Dogs should uniformly be considered to have IDDM and treatment with insulin should be initiated unless there is a strong suspicion of diabetes mellitus secondary to a concurrent insulin-antagonistic disorder (e.g., intact bitch in diestrus).

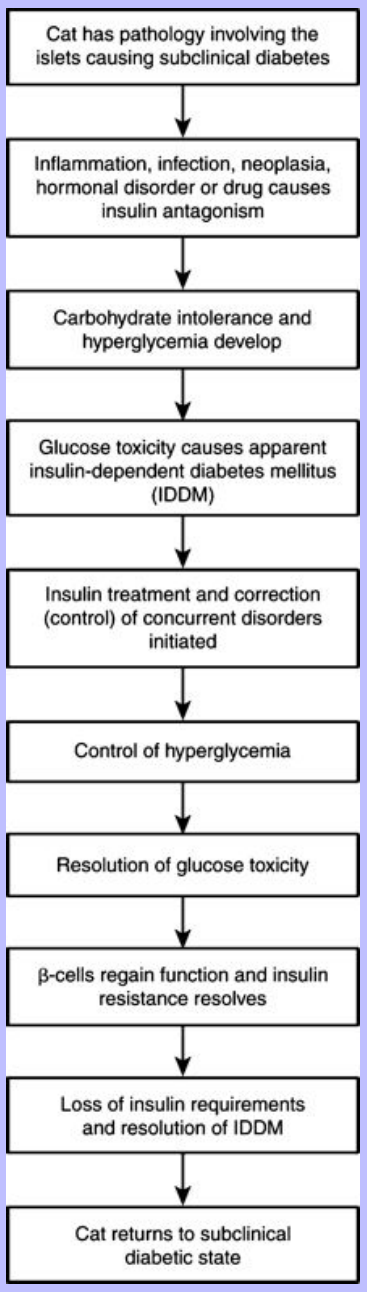
Because of the significant incidence of NIDDM and transient diabetes in cats and the successful treatment of some diabetic cats with diet and oral hypoglycemic drugs, it would be advantageous to be able to prospectively differentiate IDDM from NIDDM in cats. Unfortunately, measurements of the serum insulin concentration at baseline and after administration of an insulin secretagogue have not been consistent aids in the differentiation of IDDM from NIDDM in the cat.[4,5] A fasting serum insulin concentration greater than the normal mean concentration (greater than 12 μU/mL in our laboratory) or any postsecretagogue insulin concentration greater than one standard deviation (SD) above the reference mean (greater than 18 μU/mL in our laboratory) suggests the existence of functional beta cells and the possibility for NIDDM. Unfortunately, cats subsequently identified has having IDDM and many of those with NIDDM have a low baseline serum insulin concentration and do not respond to a glucose or glucagon challenge.[4,5,30] This apparent insulin deficiency in cats subsequently identified with NIDDM is presumably the result of concurrent glucose toxicity (see Transient Diabetes Mellitus). The ultimate differentiation of IDDM from NIDDM is often made retrospectively, after the clinician has had several weeks to assess the cat's response to therapy and to determine the animal's need for insulin. The initial decision between insulin treatment and oral hypoglycemic drugs is based on the severity of the clinical signs, the presence or absence of ketoacidosis, the cat's general health, and the owner's wishes.

241.2 PATHOPHYSIOLOGY

241.2.1 Nonketotic Diabetes Mellitus

Diabetes mellitus results from a relative or absolute deficiency of insulin secretion by the beta cells. Insulin deficiency in turn causes decreased tissue utilization of glucose, amino acids, and fatty acids; accelerated hepatic glycogenolysis and gluconeogenesis; and accumulation of glucose in the circulation, resulting in hyperglycemia. Glucose obtained from the diet also accumulates in the circulation. As the blood glucose concentration increases, the ability of the renal tubular cells to resorb glucose from the glomerular ultrafiltrate is exceeded, resulting in glycosuria. In dogs this typically occurs whenever the blood glucose concentration exceeds 180 to 220 mg/dL. The threshold for glucose resorption appears more variable in cats, ranging from 200 to 280 mg/dL. Glycosuria creates an osmotic diuresis, causing polyuria. Compensatory polydipsia prevents dehydration. The diminished peripheral tissue utilization of ingested glucose results in weight loss as the body attempts to compensate for perceived “starvation.”

Figure 241-4 Sequence of events in the development and resolution of an insulin-requiring diabetic episode in cats with transient diabetes. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders, 2004, p 546.)



The interaction of the "satiety center" in the ventromedial region of the hypothalamus with the "feeding center" in the lateral region of the hypothalamus is responsible for controlling the amount of food ingested.[33] The feeding center, responsible for evoking eating behavior, is chronically functioning but can be transiently inhibited by the satiety center after food ingestion. The amount of glucose entering the cells in the satiety center directly affects the feeling of hunger; the more glucose that enters these cells, the less the feeling of hunger and vice versa. The ability of glucose to enter the cells in the satiety center is mediated by insulin. In diabetics with a relative or absolute lack of insulin, glucose does not enter satiety center cells, resulting in failure to inhibit the feeding center. Thus these individuals become polyphagic despite hyperglycemia.

The four classic signs of diabetes mellitus are polyuria, polydipsia, polyphagia, and weight loss. The severity of these signs is directly related to the severity of hyperglycemia. As these signs become obvious to the owner, the pet is brought to the veterinarian for care.

241.2.2 Ketoacidosis

Unfortunately, some cats and dogs are not identified by their owners as having signs of disease, and these untreated diabetics may ultimately develop diabetic ketoacidosis (DKA). Ketone bodies (i.e., acetoacetate, beta hydroxybutyrate, and acetone) are derived from oxidation of nonesterified or free fatty acids (FFAs) by the liver and are used as an energy source by many tissues during periods of glucose deficiency. The most important regulators of ketone body production are FFA availability and the ketogenic capacity of the liver.[34] For synthesis of ketone bodies to be enhanced, two major alterations in intermediary metabolism must occur: (1) mobilization of FFAs from triglycerides stored in adipose tissue must be enhanced, and (2) a shift in hepatic metabolism must occur from fat synthesis to fat oxidation and ketogenesis.[35,36] Insulin is a powerful inhibitor of lipolysis and FFA oxidation. A relative or absolute deficiency of insulin "allows" lipolysis to increase, thus increasing the availability of FFAs to the liver and in turn promoting ketogenesis.

Virtually all dogs and cats with DKA have a relative or absolute deficiency of insulin. In most dogs and cats with newly diagnosed DKA, circulating insulin concentrations are low or undetectable. Some dogs and cats have serum insulin concentrations similar to those observed in normal, fasted nondiabetics (i.e., 5 to 20 μU/mL). However, such insulin concentrations are inappropriately low ("relative" insulin deficiency) for the severity of hyperglycemia encountered. Some diabetic dogs and cats develop ketoacidosis despite receiving daily injections of insulin, and circulating insulin concentrations may even be increased. In this group, a "relative" insulin deficiency is also present, presumably because of concurrent insulin resistance caused by an increase in circulating glucose counter-regulatory hormones (i.e., epinephrine, glucagon, cortisol, growth hormone), increased plasma FFA and amino acid concentrations, and metabolic acidosis. With the development of insulin resistance, the need for insulin may exceed the daily injected insulin dose, leading to a predisposition to the development of DKA.

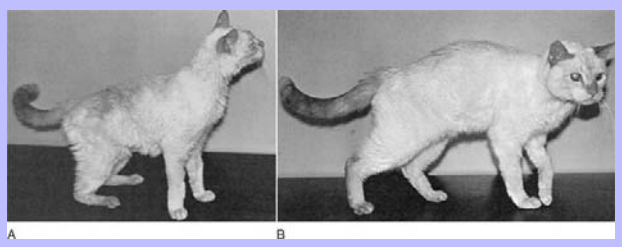
Circulating levels of the glucose counter-regulatory hormones typically are markedly increased in humans with DKA and presumably are in dogs and cats as well.[37] The body increases its production of the glucose counter-regulatory hormones in response to a wide variety of diseases and stress situations, such as pancreatitis, infection, renal insufficiency, and concurrent hormonal disorder. The net effects of these hormonal disturbances are accentuation of insulin deficiency through the development of insulin resistance; stimulation of lipolysis, leading to ketogenesis; and stimulation of gluconeogenesis, which worsens hyperglycemia. Recognition and treatment of disorders that coexist with diabetic ketoacidosis are critically important to the successful management of DKA.

The physiologic derangements that accompany DKA are a direct result of relative or absolute insulin deficiency, hyperketonemia, and hyperglycemia. Increasing plasma ketone concentrations eventually surpass the renal tubular threshold for complete resorption and spill into the urine, contributing to the osmotic diuresis caused by glycosuria and enhancing the excretion of solutes (e.g., sodium, potassium, and magnesium). 1568 1569 Insulin deficiency per se also contributes to the excessive renal losses of water and electrolytes. The result is an excessive loss of electrolytes and water, leading to volume contraction, underperfusion of tissues, and prerenal azotemia. As ketones continue to accumulate in the blood, the body's buffering system becomes overwhelmed, and progressively worsening metabolic acidosis results. Further loss of water and electrolytes occurs as a result of repeated bouts of vomiting or diarrhea combined with a lack of fluid intake, problems that often develop as the metabolic acidosis worsens. Excessive loss of electrolytes and water leads to further volume contraction, underperfusion of tissues, and worsening prerenal azotemia and dehydration. Renal excretion of glucose and to a lesser degree hydrogen ions becomes impaired, allowing glucose and ketones to accumulate in the vascular space more quickly. The result is increasing hyperglycemia and ketonemia and worsening metabolic acidosis. The rise in the blood glucose concentration raises the plasma osmolality, and the resulting osmotic diuresis further aggravates the rise in plasma osmolality by causing water losses in excess of the salt loss. The increase in plasma osmolality causes water to be shifted out of cells, leading to cellular dehydration and the eventual development of obtundation and coma. The severe metabolic consequences of DKA, which include severe acidosis, hyperosmolality, obligatory osmotic diuresis, dehydration, and electrolyte derangements, ultimately become life-threatening.

241.3 SIGNALMENT

Diabetes mellitus typically occurs in older dogs and cats, with a peak prevalence at 7 to 9 years of age in dogs and 9 to 11 years in cats.[1,12] Juvenile-onset diabetes occurs in dogs and cats less than 1 year of age and is uncommon. In dogs, females are affected about twice as often as males, whereas in cats, diabetes occurs predominately in neutered males.[1,12] Genetic predispositions for or against the development of diabetes have been suggested by familial associations in dogs and by pedigree analysis of keeshonden (see Table 241-1).[6,7] No apparent breed predisposition is seen in cats, although Burmese cats may be over-represented in Australia.[38]

Figure 241-5 **A,** Plantigrade posture in a cat with diabetes mellitus and exocrine pancreatic insufficiency. **B,** Resolution of hindlimb weakness and plantigrade posture after glycemic control was improved by adjustment of insulin therapy and initiation of pancreatic enzyme replacement therapy. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders, 2004, p 548.)



241.4 ANAMNESIS

The history in virtually all diabetic animals includes the classic polydipsia, polyuria, polyphagia, and weight loss. Owners often bring a dog to the veterinarian because the pet can no longer make it through the night without having to be let outside to urinate or because it begins urinating in the home. A common complaint of cat owners is the constant need to change the litter and an increase in the size of the kitty litter clumps; problems that reflect the polyuria associated with diabetes mellitus. Additional clinical signs in cats include lethargy; decreased interaction with family members; lack of grooming behavior and the development of a dry, lusterless, unkempt, or matted haircoat; and decreased jumping ability, rear limb weakness, or the development of a plantigrade posture (Figure 241-5). Occasionally a dog owner may be concerned about sudden blindness caused by cataract formation. The classic signs of diabetes mellitus may have gone unnoticed or may have been considered irrelevant by the owner. If the clinical signs associated with uncomplicated diabetes are not observed by the owner, a diabetic dog or cat is at risk for developing systemic signs of illness (i.e., lethargy, anorexia, vomiting, weakness) as progressive ketonemia and metabolic acidosis develop. The time sequence from onset of initial clinical signs to development of DKA is unpredictable, ranging from a few days to several months.

241.5 PHYSICAL EXAMINATION

A thorough physical examination is imperative in any dog or cat suspected of having diabetes mellitus, in part because of the high prevalence of concurrent disorders that can affect the response to treatment. Physical examination findings in a dog or cat with newly diagnosed diabetes depend on whether DKA is present and if so, its severity; on the duration of diabetes prior to diagnosis; and on the nature of any other concurrent disorders. The nonketotic diabetic dog or cat has no classic physical examination findings. Many diabetic dogs and cats are obese but are otherwise in good physical condition. Dogs and cats with prolonged untreated diabetes may have lost weight but are rarely emaciated unless concurrent disease (e.g., pancreatic exocrine insufficiency, hyperthyroidism) is present. Lethargy may be evident. The haircoat of newly diagnosed or poorly controlled diabetic dogs may be sparse, with dry, brittle, lusterless hairs, as well as scales from hyperkeratosis; diabetic cats often stop grooming and develop a dry, lusterless haircoat. Diabetes-induced hepatic lipidosis may cause hepatomegaly. Lenticular changes consistent with cataract formation are another common clinical finding in diabetic dogs. Impaired ability to jump, weakness in the rear limbs, ataxia, or a plantigrade posture (i.e., the hocks touch the ground when the cat walks) may be evident in cats that develop diabetic neuropathy (see Figure 241-5). The distal muscles of the rear limbs may feel hard on digital palpation, and cats may object to palpation or manipulation of the rear limbs, presumably because of pain associated with the neuropathy.

1569
1570

In the ketoacidotic diabetic dog or cat, physical examination findings include dehydration, depression, weakness, tachypnea, and sometimes a strong odor of acetone on the breath. With severe metabolic acidosis, slow, deep breathing (i.e., Kussmaul respiration) may be observed. Gastrointestinal signs of vomiting, abdominal pain, and distention may be present, and dogs and cats that develop severe hyperosmolarity are often extremely lethargic and may be comatose.

241.6 ESTABLISHING THE DIAGNOSIS OF DIABETES MELLITUS

A diagnosis of diabetes mellitus requires the presence of appropriate clinical signs (i.e., polyuria, polydipsia, polyphagia, weight loss) and documentation of persistent fasting hyperglycemia and glycosuria. Measurement of the blood glucose concentration using a portable blood glucose monitoring device and testing for the presence of glycosuria using urine reagent test strips (e.g., KetoDiastix; Ames Division, Miles Laboratories, Elkhart, Indiana)

allow rapid confirmation of a diagnosis of diabetes mellitus. Concurrent documentation of ketonuria establishes a diagnosis of diabetic ketosis or ketoacidosis.

It is important to document both persistent hyperglycemia and glycosuria to establish a diagnosis of diabetes mellitus, because hyperglycemia differentiates diabetes mellitus from primary renal glycosuria, whereas glycosuria differentiates diabetes mellitus from other causes of hyperglycemia (Box 241-2). Transient, stress-induced hyperglycemia is a common problem in cats and can cause the blood glucose concentration to increase above 300 mg/dL. Unfortunately, stress is a subjective state that cannot be accurately measured, it is not always easily recognized, and it may evoke inconsistent responses among individual cats. Glycosuria usually does not develop in cats with stress hyperglycemia because the transient increase in the blood glucose concentration prevents glucose from accumulating in urine to a detectable concentration. However, hyperglycemia and glycosuria can occur secondary to stress in cats. For this reason, the clinician should always document persistent hyperglycemia and glycosuria when establishing a diagnosis of diabetes mellitus in cats. If doubt exists, the "stressed" cat can be sent home with instructions for the owner to monitor the urine glucose concentration with the cat in the nonstressed home environment. Alternatively, a serum fructosamine concentration can be measured. Documentation of an increase in the serum fructosamine concentration supports the presence of sustained hyperglycemia; however, a serum fructosamine concentration in the upper range of normal can occur in symptomatic diabetic cats if the diabetes developed shortly before the cat was brought to the veterinarian.[39]

Mild hyperglycemia (i.e., 130 to 180 mg/dL) is clinically silent and is usually an unexpected and unsuspected finding. If the dog or cat with mild hyperglycemia is examined for polyuria and polydipsia, a disorder other than clinical diabetes mellitus should be sought. Mild hyperglycemia can occur up to 2 hours postprandial in some dogs and cats, in "stressed" dogs and cats, in early diabetes mellitus, and with disorders causing insulin resistance. A diagnostic evaluation for disorders causing insulin resistance is indicated if mild hyperglycemia persists in the fasted, unstressed dog or cat. Insulin therapy is not indicated in these animals because clinical diabetes mellitus is not present.

241.7 PATIENT EVALUATION

241.7.1 Nonketotic Diabetic Animal

A thorough clinicopathologic evaluation is recommended once the diagnosis of diabetes mellitus has been established. The clinician must be aware of any disease that might be causing or contributing to carbohydrate intolerance (e.g., hyperadrenocorticism), that may result from carbohydrate intolerance (e.g., bacterial cystitis), or that may force modification of therapy (e.g., pancreatitis). The minimum laboratory evaluation in any "healthy" nonketotic diabetic dog or cat should include a complete blood count (CBC), serum biochemical panel, serum thyroxine concentration (cat), and urinalysis with bacterial culture. The serum progesterone concentration should be determined if diabetes mellitus is diagnosed in an intact bitch, regardless of her cycling history. If available, abdominal ultrasonography is indicated to assess for pancreatitis, adrenomegaly, pyometritis in an intact bitch or queen, and abnormalities affecting the liver and urinary tract. Because of the relatively high prevalence of pancreatitis in diabetic dogs and cats, measurement of serum lipase or serum trypsin-like immunoreactivity (TLI) or serum pancreatic lipase immunoreactivity (PLI) should be considered

if abdominal ultrasonography is not available. Measurement of the baseline serum insulin concentration or an insulin response test is not routinely done, although it may be considered in cats prior to treatment with oral hypoglycemic drugs (see Diagnosis of Insulin-Dependent versus Noninsulin-Dependent Diabetes Mellitus). 1570
Additional tests may be warranted after the history has been obtained, the physical examination has been performed, or ketonuria has been identified. Potential clinicopathologic abnormalities are listed in Box 241-3. 1571

241.7.2 Ketoacidotic Diabetic Animal

The laboratory evaluation of apparently healthy dogs and cats with both glucose and ketones present in the urinalysis is similar to that for the nonketotic diabetic patient. The healthy ketotic diabetic can usually be managed conservatively, without fluid therapy or intensive care. In contrast, sick ketoacidotic diabetic dogs and cats are critical metabolic emergencies that require a much more aggressive therapeutic plan. To aid in the formulation of an appropriate treatment protocol, a group of critically important studies must be performed, including urinalysis, hematocrit, total plasma protein concentration, blood glucose, venous total carbon dioxide (CO_2) or arterial acid-base evaluation, blood urea nitrogen or serum creatinine, and serum electrolytes (sodium [Na], potassium [K], calcium [Ca], and phosphate [PO_4]). The results of these tests guide the proper choice of fluid therapy, as well as corrections that must be made with respect to electrolyte alterations, acidosis, and renal function. Additional data, such as radiographs, abdominal ultrasound scans, or further clinical pathologic studies, may be needed, depending on the results of the history and physical examination and the nature of concurrent disorders.

241.7.2.1 Box • 241-3 Clinicopathologic Abnormalities Commonly Found in Dogs and Cats with Uncomplicated Diabetes Mellitus

241.7.2.1.1 Complete Blood Count

Typically normal

Neutrophilic leukocytosis, toxic neutrophils (with pancreatitis or infection)

241.7.2.1.2 Biochemistry Panel

Hyperglycemia

Hypercholesterolemia

Hypertriglyceridemia (lipemia)

Increased alanine aminotransferase activity (typically <500 IU/L)

Increased alkaline phosphatase activity (typically <500 IU/L)

241.7.2.1.3 Urinalysis

Urine specific gravity typically >1.025

Glycosuria

Variable ketonuria

Proteinuria

Bacteriuria

241.7.2.1.4 Ancillary Tests

Hyperlipasemia (with pancreatitis)

Hyperamylasemia (with pancreatitis)

Serum trypsin-like immunoreactivity

- Usually normal
- Low with pancreatic exocrine insufficiency
- High with acute pancreatitis
- Normal to high with chronic pancreatitis

Serum pancreatic lipase immunoreactivity

- Usually normal
- Low with pancreatic exocrine insufficiency
- High with pancreatitis

Variable serum baseline insulin concentration

- Insulin-dependent diabetes mellitus: Low, normal
- Non-insulin-dependent diabetes mellitus: Low, normal, increased
- Insulin resistance induced: Low, normal, increased

241.8 THERAPY FOR THE ILL DIABETIC KETOACIDOTIC PATIENT

An aggressive therapeutic plan (Box 241-4) is indicated if the dog or cat has systemic signs of illness (i.e., lethargy, anorexia, vomiting); if the physical examination reveals dehydration, depression, weakness, and/or Kussmaul respiration; if the blood glucose concentration is greater than 500 mg/dL; or if severe metabolic

acidosis is present, as diagnosed by a total venous CO_2 or arterial bicarbonate concentration less than 12 mEq/L.

The goals of treatment for a severely ill, ketoacidotic, diabetic pet are (1) to provide adequate amounts of insulin to normalize intermediary metabolism, (2) to restore water and electrolyte losses, (3) to correct the acidosis, (4) to identify precipitating factors for the current illness, and (5) to provide a carbohydrate substrate when required by the insulin treatment. Proper therapy does not imply forcing as rapid a return to normal as possible. Because osmotic and biochemical problems can be created by overly aggressive therapy, as well as by the disease process itself, rapid changes in various vital parameters can be as harmful as or more harmful than no change. If all abnormal parameters can be slowly moved toward normal (i.e., over 36 to 48 hours), the likelihood of successful therapy is greater.

241.8.1 ## Fluid Therapy

Initiation of appropriate fluid therapy should be the first step in the treatment of DKA. Replacement of fluid deficiencies and maintenance of normal fluid balance are important for ensuring adequate cardiac output, blood pressure, and blood flow to all tissues. Improvement of renal blood flow is especially critical. In addition to the general beneficial aspects of fluid therapy in any dehydrated animal, fluid therapy can correct the deficiencies in total body sodium and potassium, dampening the potassium-lowering effect of insulin treatment. Fluid therapy can reduce blood glucose concentrations in diabetics even without insulin administration. Unfortunately, fluid therapy alone does not decrease the concentrations of acetoacetate and beta hydroxybutyrate or improve the severity of metabolic acidosis. For these reasons, insulin is always required.

The type of parenteral fluid initially used depends on the electrolyte status, blood glucose concentration, and osmolality. Most dogs and cats with DKA have severe deficits in total body sodium, regardless of the measured serum concentration. Unless serum electrolyte concentrations dictate otherwise, the initial intravenous fluid of choice is 0.9% sodium chloride with appropriate potassium supplementation. Most dogs and cats with severe DKA usually are sodium depleted and therefore are not suffering from dramatic hyperosmolality despite potentially remarkable increases in the blood glucose concentration. Other replacement crystalloid solutions that can be used if physiologic (0.9%) saline is not available are Ringer's solution, Ringer's lactated solution, Plasma-Lyte 148 (Baxter Healthcare, Deerfield, Illinois), and Normosol-R (Abbott Laboratories, Chicago, Illinois). Hypotonic fluids (e.g., 0.45% saline) are rarely indicated in dogs and cats with DKA even with severe hyperosmolality. Hypotonic fluids do not provide adequate amounts of sodium to correct the sodium deficiency. Rapid administration of hypotonic fluids can also cause a rapid decrease in plasma osmolality, which may result in cerebral edema, deterioration in mentation, and eventually coma. Hyperosmolality is best treated with isotonic fluids and judicious administration of insulin.

1571 1572

241.8.1.1 ### Box • 241-4 Initial Management of the Dog or Cat with Severe Diabetic Ketoacidosis

241.8.1.1.1 #### Fluid Therapy

Type: 0.9% saline solution initially.

Rate: 60 to 100 mL/kg/24 hr initially; adjust based on hydration status, urine output, and persistence of fluid losses.

Potassium supplementation: Based on serum potassium (K^+) concentration; if concentration is unknown, initially add 40 mEq KCl to each liter of fluids.

Phosphate supplementation: Administer if serum phosphorus concentration is less than 1.5 mg/dL or if hemolytic anemia develops; initial IV infusion rate is 0.01 to 0.03 mmol/kg/hr in calcium-free fluids (e.g., 0.9% saline).

Dextrose supplementation: Not indicated until blood glucose concentration approaches 250 mg/dL; then begin 5% dextrose infusion.

241.8.1.1.2 Bicarbonate Therapy

Indication: Administer if plasma bicarbonate concentration is less than 12 mEq/L or total venous carbon dioxide (CO_2) concentration is less than 12 mmol/L; if concentration is unknown, do not administer unless animal is severely ill, and then give only once.

Amount: HCO_3^- (mEq) = Body weight (kg) × 0.4 × (12–Patient's HCO_3^-) × 0.5; if patient's HCO_3^- or total CO_2 concentration is unknown, use 10 in place of (12–Patient's HCO_3^-).

Administration: Add to IV fluids and give over 6 hours; do not give as bolus infusion.

Retreatment: Only if plasma bicarbonate concentration remains less than 12 mEq/L after 6 hours of therapy.

241.8.1.1.3 Insulin Therapy

Type: Regular crystalline insulin.

Administration

- Intermittent intramuscular (IM) technique: Initial dose, 0.2 U/kg IM; then 0.1 U/kg IM hourly until blood glucose concentration approaches 250 mg/dL; then switch to subcutaneous (SC) regular insulin q6-8h.
- Low-dose intravenous (IV) infusion technique: Initial rate, 0.05 to 0.1 U/kg/hr diluted in 0.9% sodium chloride and administered via infusion or syringe pump in a line separate from that used for fluid therapy; adjust infusion rate based on hourly blood glucose measurements; switch to SC regular insulin q6-8h once blood glucose concentration approaches 250 mg/dL. Decrease the hourly IM insulin dose or the IV insulin infusion rate for the initial 2 to 3 hours of treatment if the dog or cat is hypokalemic at the time of diagnosis.

Goal: Gradual decline in the blood glucose concentration (preferably at a rate of about 75 mg/dL/hr) until the concentration is less than 250 mg/dL.

241.8.1.1.4 Ancillary Therapy

Concurrent pancreatitis is common in diabetic ketoacidosis (DKA); nothing per os and aggressive fluid therapy usually are indicated.

Concurrent infections are common in DKA; broad-spectrum parenteral antibiotics usually are indicated.

Additional therapy may be needed, depending on the nature of concurrent disorders.

241.8.1.1.5 Patient Monitoring

Blood glucose measurement every 1 to 2 hours initially; adjust insulin therapy and begin dextrose infusion when the concentration approaches 250 mg/dL.

Hydration status, respiration, and pulse every 2 to 4 hours; adjust fluids accordingly.

Serum electrolyte and total venous CO_2 concentrations every 6 to12 hours; adjust fluid and bicarbonate therapy accordingly.

Urine output, glycosuria, and ketonuria every 2 to 4 hours; adjust fluid therapy accordingly.

Body weight, packed cell volume, temperature, and blood pressure daily.

Additional monitoring, depending on concurrent diseases.

Fluid administration should be directed toward gradual replacement of hydration deficits over 24 hours while maintenance fluid needs are supplied and ongoing losses are matched. Rapid replacement of fluids is rarely indicated unless the dog or cat is in shock. Once the animal is out of this critical phase, fluid replacement should be decreased in an effort to correct the fluid imbalance in a slow but steady manner. As a general rule, a fluid rate of one and one half to two times maintenance (i.e., 60 to 100 mL/kg/24 hr) is chosen initially, and subsequent adjustments are based on frequent assessment of hydration status, urine output, severity of azotemia, and persistence of vomiting and diarrhea.

241.8.2 Potassium Supplementation

Most dogs and cats with DKA initially have either normal or decreased serum potassium concentrations. During therapy for DKA, the serum potassium concentration may decrease because of rehydration (dilution), insulin-mediated cellular uptake of potassium (with glucose), continued urinary losses, and correction of acidemia (translocation of potassium into the intracellular fluid [ICF] compartment). Dogs and cats with hypokalemia require aggressive potassium replacement therapy to replace deficits and to prevent worsening, life-threatening hypokalemia after initiation of insulin therapy. The exception to potassium supplementation of fluids is hyperkalemia associated with oliguric renal failure. Potassium supplementation should initially be withheld in these dogs and cats until glomerular filtration has been restored, urine production increases, and hyperkalemia is resolving.

1572 1573

Ideally the amount of potassium required is based on actual measurement of the serum potassium concentration. If an accurate measurement of serum potassium is not available, 40 mEq of potassium should be added initially to each liter of intravenous fluids (36 mEq should be added to Ringer's solution). Subsequent adjustments in potassium supplementation should be based on measurement of the serum potassium concentration, preferably every 6 to 8 hours until the dog or cat is stable and serum electrolyte values are in the normal range.

241.8.3 Phosphate Supplementation

Most dogs and cats with DKA have either normal or decreased serum phosphorus concentrations on pretreatment testing. Within 24 hours of initiation of treatment for DKA, the serum phosphorus concentration can decrease to worrisome levels (i.e., less than 1 mg/dL) as a result of the dilutional effects of fluid therapy,

the intracellular shift of phosphorus after initiation of insulin therapy, and continuing renal and gastrointestinal loss.[40] Hypophosphatemia affects primarily the hematologic and neuromuscular systems in dogs and cats. Hemolytic anemia is the most common problem and can be life-threatening if not recognized and treated. Weakness, ataxia, and seizures may also be observed. Severe hypophosphatemia may be clinically silent in many animals.

Phosphate therapy is indicated if clinical signs or hemolysis are identified or if the serum phosphorus concentration decreases to less than 1.5 mg/dL. Phosphate is supplemented by means of intravenous infusion. Potassium and sodium phosphate solutions contain 3 mmol of phosphate and either 4.4 mEq of potassium or 4 mEq of sodium per milliliter. The recommended dosage for phosphate supplementation is 0.01 to 0.03 mmol of phosphate per kilogram of body weight per hour, preferably administered in calcium-free intravenous fluids (e.g., 0.9% sodium chloride).[40] In dogs and cats with severe hypophosphatemia, the dosage may need to be increased to 0.03 to 0.12 mmol/kg/hr.[41] Because the dose of phosphate needed to replete an animal and the animal's response to therapy cannot be predicted, it is important initially to monitor the serum phosphorus concentration every 8 to 12 hours and to adjust the phosphate infusion accordingly. Adverse effects from overzealous phosphate administration include iatrogenic hypocalcemia and its associated neuromuscular signs, hypernatremia, hypotension, and metastatic calcification. The serum total (or preferably ionized) calcium concentration should be measured at the same time as the serum phosphorus concentration, and the rate of phosphate infusion should be decreased if hypocalcemia is identified. Phosphorus supplementation is not indicated in dogs and cats with hypercalcemia, hyperphosphatemia, oliguria, or suspected tissue necrosis. If renal function is in question, phosphorus should not be supplemented until the status of renal function and the serum phosphorus concentration are known.

241.8.4 Magnesium Supplementation

Hypomagnesemia is common in dogs and cats with DKA; it often worsens during the initial treatment of DKA but resolves without treatment as the DKA resolves.[42] Clinical signs of hypomagnesemia do not usually occur until the serum total and ionized magnesium concentration is less than 1 and 0.5 mg/dL, respectively, and even at these low levels, many dogs and cats remain asymptomatic. We do not routinely treat hypomagnesemia in dogs or cats with DKA unless problems with persistent lethargy, anorexia, weakness, or refractory hypokalemia or hypocalcemia are encountered after 24 to 48 hours of fluid and insulin therapy or some other cause of the problem cannot be identified.

241.8.5 Bicarbonate Therapy

The physical examination results, in conjunction with the plasma bicarbonate or total venous CO_2 concentration, should be used to determine the need for bicarbonate therapy. Bicarbonate supplementation is not recommended when the plasma bicarbonate (or total venous CO_2) concentration is 12 mEq/L or greater, especially if the animal is alert. An alert dog or cat probably has a normal or near-normal pH in the cerebrospinal fluid (CSF). The acidosis in these animals is corrected through insulin administration and fluid therapy. Improvement in renal perfusion enhances urinary loss of ketoacids, and insulin therapy markedly diminishes the production of ketoacids. Acetoacetate and beta hydroxybutyrate are also metabolically usable anions, and 1 mEq of bicarbonate is generated from each 1 mEq of ketoacid metabolized.

When the plasma bicarbonate concentration is 11 mEq/L or less (total venous CO_2 is below 12 mEq/L), bicarbonate therapy should be initiated. Many of these animals have severe depression that may be a result of concurrent severe central nervous system (CNS) acidosis. Metabolic acidosis should be corrected slowly to

avoid major alterations in the pH of the CSF. Only a portion of the bicarbonate deficit is given initially, over a 6-hour interval. The bicarbonate deficit (i.e., the milliequivalents of bicarbonate initially needed to correct acidosis to the critical level of 12 mEq/L over a period of 6 hours) is calculated as:

$$\text{Bicarbonate (mEq)} = \text{Body weight (kg)} \times 0.4 \times (12 - \text{Patient's bicarbonate measurement}) \times 0.5$$

or, if the serum bicarbonate is not known:

$$\text{Bicarbonate (mEq)} = \text{Body weight (kg)} \times 2$$

The difference between the animal's serum bicarbonate concentration and the critical value of 12 mEq/L represents the treatable base deficit in DKA. If the animal's serum bicarbonate concentration is not known, 10 should be used for the treatable base deficit. The factor 0.4 corrects for the extracellular fluid space in which bicarbonate is distributed (40% of body weight). The factor 0.5 provides one half of the required dose of bicarbonate in the intravenous (IV) infusion. In this manner, a conservative dose is given over a 6-hour period. Bicarbonate should *never* be given by bolus infusion. After 6 hours of therapy, the acid-base status should be re-evaluated and a new dose calculated. Once the plasma bicarbonate concentration is greater than 12 mEq/L, further bicarbonate supplementation is usually not needed.

241.8.6 Insulin Therapy

Insulin therapy is critical for the resolution of ketoacidosis. However, overzealous insulin treatment can cause severe hypokalemia, hypophosphatemia, and hypoglycemia during the first 24 hours of treatment. These are problems that can be minimized by appropriate fluid therapy, frequent monitoring of serum electrolytes and blood glucose concentrations, and modification of the initial insulin treatment protocol as indicated. The decision on when to start insulin therapy varies with the experiences of the veterinarian queried. Initiation of appropriate fluid therapy should always be the first step in the treatment of DKA. Delaying insulin therapy allows the benefits of fluid therapy to begin to be realized before the glucose-, potassium-, and phosphorus-lowering effects of insulin therapy commence. The question is how long to delay insulin therapy. The author typically delays insulin therapy for a minimum of 1 to 2 hours. Additional delays and decisions on the initial dosage of insulin are based on the serum electrolyte results. If the serum potassium concentration is within the normal range after 2 hours of fluid therapy, the author begins insulin treatment as described below. If hypokalemia persists, insulin therapy can be delayed an additional 1 to 2 hours to allow fluid therapy to replenish potassium, or the initial insulin dose can be reduced to dampen the intracellular shift of potassium and phosphorus. The more severe the hypokalemia, the more inclined the author is to delay insulin therapy and to reduce the initial insulin dose. However, insulin therapy should always be started within 4 hours of initiation of fluid therapy.

1573 1574

Insulin protocols for the treatment of DKA include the hourly intramuscular (IM) technique, the continuous low-dose IV infusion technique, and the intermittent IM then subcutaneous (SC) technique. All three routes of insulin administration (IV, IM, SC) are effective in decreasing the plasma glucose and ketone concentrations. Successful management of DKA does *not* depend on the route of insulin administration; rather, it depends on proper treatment of each disorder associated with DKA.

241.8.6.1 Hourly intramuscular insulin technique

Dogs and cats with severe DKA should receive an initial regular crystalline insulin loading dose of 0.2 U/kg, followed by 0.1 U/kg every hour thereafter. The insulin dose can be reduced by 25% to 50% for the

first two or three injections if hypokalemia is a concern. The insulin should be administered into the muscles of the rear legs to ensure that the injections are intramuscular and not going into fat or subcutaneous tissue. Dilution of regular insulin 1:10 with sterile saline and the use of 0.3 mL U100 insulin syringes are helpful when small doses of insulin are required. The blood glucose concentration should be measured every hour with a point-of-care chemistry analyzer or portable blood glucose monitoring device, and the insulin dosage should be adjusted accordingly. The goal of initial insulin therapy is to lower the blood glucose concentration *slowly* to the range of 200 to 250 mg/dL, preferably over a 6-to 10-hour period; an hourly decline of 50 mg/dL is ideal.[43] This provides a steady, moderate decline and avoids large shifts in osmolality. A declining blood glucose concentration also ensures that lipolysis and the supply of FFAs for ketone production have been effectively turned off. Glucose concentrations, however, decrease much more rapidly than do ketone levels. In general, hyperglycemia is corrected within 12 hours, but ketosis often takes 48 to 72 hours to resolve.

Once the initial hourly insulin therapy brings the blood glucose concentration near 250 mg/dL, hourly administration of regular insulin should be discontinued, and regular insulin should be given intramuscularly every 4 to 6 hours or, if the hydration status is good, subcutaneously every 6 to 8 hours. The initial dosage is usually 0.1 to 0.3 U/kg, with subsequent adjustments based on blood glucose concentrations. In addition, at this point the intravenous infusion solution should have enough 50% dextrose added to create a 5% dextrose solution (100 ml of 50% dextrose added to each liter of fluids). The blood glucose concentration should be maintained between 150 and 300 mg/dL until the animal is stable and eating. Usually a 5% dextrose solution is adequate for maintaining the desired blood glucose concentration. If the blood glucose concentration dips below 150 mg/dL or rises above 300 mg/dL, the insulin dosage can be lowered or raised accordingly. Dextrose helps minimize problems with hypoglycemia and allows insulin to be administered on schedule. Delaying administration of insulin delays correction of the ketoacidotic state.

241.8.6.2 Constant low-dose insulin infusion technique

Constant intravenous infusion of regular crystalline insulin is also effective at decreasing blood glucose concentrations. The infusion is prepared by adding regular crystalline insulin (2.2 U/kg for dogs; 1.1 U/kg for cats) to 250 mL of 0.9% saline; it initially is administered at a rate of 10 mL/hr in a line separate from that used for fluid therapy.[44] This provides an insulin infusion rate of 0.05 U/kg/hr in cats and 0.1 U/kg/hr in dogs, a rate that has been shown to produce plasma insulin concentra-tions between 100 and 200 μU/mL in dogs. Because insulin adheres to glass and plastic surfaces, approximately 50 mL of the insulin-containing fluid should be run through the drip set before it is administered to the animal. The rate of insulin infusion can be reduced for the initial 2 to 3 hours if hypokalemia is a concern. Two separate catheters are recommended for treatment: a peripheral catheter for insulin administration and a central catheter for fluid administration and blood sampling. An infusion or syringe pump should be used to ensure a constant rate of insulin infusion.

Adjustments in the infusion rate are based on hourly measurements of the blood glucose concentration; an hourly decline of 50 mg/dL in the blood glucose concentration is ideal.[43] Once the blood glucose concentration approaches 250 mg/dL, the insulin infusion can be discontinued, and regular insulin can be given intramuscularly every 4 to 6 hours or, if the hydration status is good, subcutaneously every 6 to 8 hours, as discussed for the hourly IM protocol. Alternatively, the insulin infusion can be continued (at a decreased rate to prevent hypoglycemia) until the insulin preparation is exchanged for a longer acting product. Dextrose should be added to the IV fluids once the blood glucose concentration approaches 250 mg/dL, as discussed in the section on the hourly IM insulin technique.

241.8.6.3 Intermittent intramuscular/subcutaneous technique

The intermittent IM then SC insulin technique is less labor intensive than the other insulin administration techniques, but the decrease in blood glucose can be rapid and the risk of hypoglycemia is greater. The initial regular crystalline insulin dose is 0.25 U/kg given intramuscularly every 4 hours. Usually, insulin is administered intramuscularly only once or twice. Once the animal is rehydrated, subcutaneous administration is substituted for intramuscular administration, and insulin is given every 6 to 8 hours. Subcutaneous administration is not recommended initially because of problems with insulin absorption from subcutaneous sites of deposition in a dehydrated dog or cat. The dosage of IM or SC insulin is adjusted according to the blood glucose concentrations, which initially should be measured hourly beginning with the first IM injection. An hourly decline of 50 mg/dL in the blood glucose concentration is ideal.[43] Subsequent insulin dosages should be decreased by 25% to 50% if this goal is exceeded. Dextrose should be added to the IV fluids once the blood glucose concentration approaches 250 mg/dL, as discussed in the section on the hourly IM insulin technique.

241.8.6.4 Initiation of longer acting insulin

Longer acting insulin (e.g., NPH, Lente, protamine zinc insulin [PZI]) should not be administered until the dog or cat is stable, eating, maintaining fluid balance without any intravenous infusions, and no longer acidotic, azotemic, or electrolyte deficient. The initial dose of these longer acting insulins is similar to the regular insulin dose used just before the switch is made to longer acting insulin. Subsequent adjustments in the longer acting insulin dose should be based on the clinical response and measurement of blood glucose concentrations.

1574

1575

241.8.7 Concurrent Illness

Therapy for DKA frequently involves the management of concurrent, often serious illness. Common concurrent illnesses in dogs and cats with DKA are acute and chronic pancreatitis, bacterial infection, cholangiohepatitis, renal insufficiency, cardiac disease, and insulin antagonism induced by hormonal disorders, most notably iatrogenic or naturally developing hyperadrenocorticism and diestrus.[45] Modifications in therapy for DKA (e.g., fluid therapy with concurrent heart failure) and/or additional therapy (e.g., antibiotics) may be required, depending on the concurrent illness. Insulin therapy, however, should never be delayed or discontinued; resolu-tion of ketoacidosis can be obtained only through insulin therapy. If nothing is to be given by mouth, insulin therapy should be continued and the blood glucose concentration maintained with intravenous dextrose infusions. If concurrent insulin-antagonistic disease is present, correction of the disease while the animal is still ill may be necessary to improve insulin effectiveness and resolve the ketoacidosis.

241.8.8 Complications of Therapy for Diabetic Ketoacidosis

Complications induced by therapy for DKA are common and usually result from overly aggressive treatment, inadequate patient monitoring, and failure to re-evaluate biochemical parameters in a timely manner. DKA is a complex disorder with a high mortality rate if it is improperly managed. To minimize the occurrence of therapeutic complications and to improve the chance of a successful response to therapy, all abnormal parameters must be *slowly* moved toward normal (i.e., over 36 to 48 hours); the animal's physical and mental status must be evaluated frequently (at least three to four times daily); and biochemical parameters (e.g., blood

glucose, serum electrolytes, blood gases) must be evaluated in a timely fashion. During the initial 24 hours, the blood glucose concentration should be measured every 1 to 2 hours and the serum electrolytes and blood gases every 6 to 8 hours. Fluid, insulin, and bicarbonate therapies typically require modification three or four times during the initial 24 hours of therapy. Failure to recognize changes in the status of DKA and to respond accordingly can lead to potentially serious complications. The more common complications are hypoglycemia, CNS signs secondary to cerebral edema, severe hypernatremia and hyperchloremia, severe hypokalemia, and hemolytic anemia from hypophosphatemia.

241.9 THERAPY FOR THE HEALTHY DIABETIC KETOACIDOTIC PATIENT

Diabetic dogs and cats that have ketonuria but not metabolic acidosis (i.e., diabetic ketosis) are often relatively healthy aside from the typical clinical signs of uncontrolled diabetes mellitus. Diabetic ketosis may be identified in newly diagnosed diabetic dogs and cats or in diabetic dogs and cats being treated with insulin. Identification of ketonuria in insulin-treated diabetic dogs and cats indicates that insulin treatment has become ineffective, usually because of a problem with the insulin treatment regimen or because a concurrent disorder has developed that causes insulin resistance, or both. The author typically treats dogs and cats with diabetic ketosis and no systemic signs of illness with short-acting regular crystalline insulin administered subcutaneously every 8 hours until ketonuria resolves. Because regular crystalline insulin is a potent insulin, the initial dose (0.1 to 0.2 U/kg per injection) is lower than that recommended for longer acting insulin preparations. To minimize hypoglycemia, the dog or cat should be fed one third of its daily caloric intake at the time of each insulin injection. Subsequent adjustments in the insulin dose are based on the clinical response and blood glucose values. Urine ketone concentrations should also be monitored. If the blood glucose concentration is well controlled, blood and urine ketone concentrations fall. Although the time until resolution of ketonuria is quite variable, most dogs and cats are negative for urine ketones within 3 to 5 days of initiation of three times a day regular crystalline insulin therapy. However, some dogs and cats require several weeks of regular crystalline insulin treatment before excessive hepatic production of ketones resolves. Prolonged ketonuria or recurring bouts of ketonuria are suggestive of a concurrent illness that is causing insulin resistance or of hyperglucagonemia, or both. Once the ketonuria has resolved, the dog or cat is stable, and control of glycemia is acceptable, a switch to a longer acting insulin preparation administered twice a day can be tried.

241.10 THERAPY FOR THE NONKETOTIC DIABETIC PATIENT

241.10.1 Goals of Therapy

The primary goal of therapy is elimination of the owner-observed signs that occur secondary to hyperglycemia and glycosuria. Persistence of clinical signs and the development of chronic complications (Box 241-5) directly correlate with the severity and duration of hyperglycemia. Limiting blood glucose concentration fluctuations and maintaining near-normal glycemia helps both to minimize the severity of clinical signs and to prevent the complications of poorly controlled diabetes. In the diabetic dog and cat, this can be accomplished through proper insulin therapy, diet, exercise, oral hypoglycemic medications, and the prevention or control of concurrent inflammatory, infectious, neoplastic, and hormonal disorders.

Although it is worthwhile to attempt to normalize the blood glucose concentration, the veterinarian must also guard against the development of hypoglycemia, a serious and potentially fatal complication of therapy. Hypoglycemia is most apt to occur as the result of overzealous insulin therapy. The veterinarian must balance the benefits of tight glucose control obtainable with aggressive insulin therapy against the risk of hypoglycemia.

241.10.1.1 Box • 241-5 Complications of Diabetes Mellitus in Dogs and Cats

241.10.1.1.1 Common

Exocrine pancreatic insufficiency

Gastric paresis

Diabetic diarrhea

Diabetic dermatopathy (dog)

241.10.2 Initial Insulin Therapy in Dogs

Once the diagnosis of diabetes has been established, dogs should be considered to have IDDM and treatment with insulin should be initiated. Intermediate-acting insulin (i.e., NPH, Lente) is the initial insulin of choice for establishing control of glycemia in diabetic dogs (Table 241-2). Recombinant human source insulin should be used to minimize the development of anti-insulin antibodies, which may interfere with control of glycemia. Insulin therapy is begun with recombinant human NPH or Lente insulin at an approximate dosage of 0.25 U/kg given twice a day. Dietary therapy is initiated concurrently (see below). Because the overwhelming majority of diabetic dogs require NPH or Lente insulin twice a day, we prefer to start with twice daily insulin therapy.[46] Establishing control of glycemia is easier and problems with hypoglycemia and the Somogyi effect (see Insulin Overdosing and Glucose Counter-Regulation [Somogyi Phenomenon]) are less likely when twice daily therapy is initiated while the insulin dosage is low (i.e., at the time insulin treatment is initiated).

241.10.3 Initial Insulin Therapy in Cats

Diabetic cats are notoriously unpredictable in their response to exogenous insulin. No single type of insulin is routinely effective in maintaining control of glycemia, even with twice a day administration. Ultralente insulin is the longest acting but least potent of the commonly used commercial insulins. Although considered a long-acting insulin, Ultralente insulin must be administered twice a day in most diabetic cats, and its absorption is inadequate for controlling glycemia in approximately 25% of cats. PZI is a longer acting insulin that is more consistently absorbed than Ultralente insulin and that has a more acceptable duration of effect than NPH insulin. However, the timing of the glucose nadir is quite variable and occurs within 9 hours of PZI administration in greater than 80% of treated diabetic cats.[47] The author routinely administers PZI twice a day. Lente and NPH insulin are more potent insulin preparations that are more consistently and rapidly absorbed after subcutaneous administration than is Ultralente insulin. Unfortunately, the duration of effect for Lente and especially NPH insulin can be considerably shorter than 12 hours in some diabetic cats, resulting in inadequate control of glycemia despite twice daily administration.

It is not possible to predict which type of insulin will work best in individual diabetic cats. The initial insulin of choice ultimately is based on the veterinarian's personal preference and experience. Currently, the author recommends either Lente insulin of recombinant human origin or PZI of beef/pork origin at a dosage of 1 to 2 U per cat administered twice daily. Dietary therapy is initiated concurrently (see below). Although the amino acid sequences of human and feline insulin differ, prevalence of insulin antibodies causing problems with control of glycemia is uncommon in cats treated with recombinant human insulin. Because greater than 80% to 90% of diabetic cats require recombinant human Lente insulin or beef/pork PZI twice a day, the author prefers to start with twice a day insulin therapy. Establishing control of glycemia is easier and problems with hypoglycemia and the Somogyi effect are less likely when twice daily insulin therapy is initiated while the insulin dosage is low (i.e., at the time insulin treatment is initiated).

Table • 241-2 Properties of Recombinant Human Insulin Preparations Used in Diabetic Dogs and Cats* and of Beef/Pork Protamine Zinc Insulin (PZI) Used in Diabetic Cats

			TIME OF MAXIMUM EFFECT POST INSULIN-ADMINISTRATION (hr)		DURATION OF EFFECT (hr)	
INSULIN TYPE	ROUTE OF ADMINISTRATION	ONSET OF EFFECT	DOG	CAT	DOG	CAT
Regular crystalline	Intravenous	Immediate	½-2	½-2	1–4	1–4
	Intramuscular	10–30 min	1–4	1–4	3–8	3–8
	Subcutaneous	10–30 min	1–5	1–5	4–10	4–10
NPH†	Subcutaneous	½-2 hr	2–10	2–8	6–18	4–12
Lente†‡	Subcutaneous	½-2 hr	2–10	2–10	8–20	6–18
Ultralente	Subcutaneous	½-8 hr	4–16	4–16	8–24	6–24
PZI‡	Subcutaneous	½-4 hr	—	4–14	—	6–20

* Purified pork insulin has similar properties; beef/pork insulin mixtures are less potent and may have a longer duration of action than recombinant human insulins.

† Initial insulin of choice for the diabetic dog.

‡ Initial insulin of choice for the diabetic cat.

Insulin glargine (Lantus; Aventis Pharmaceuticals, Bridgewater, New Jersey) is a long-acting insulin analog that forms microprecipitates at the site of injection, from which small amounts of insulin glargine are slowly released. Insulin glargine is currently recommended as a basal insulin (i.e., sustained long-acting insulin to inhibit hepatic glucose production) administered once a day at bedtime in human diabetics.[48,49] In a preliminary study involving healthy cats, most of the pharmacokinetic and pharmacodynamic properties were similar for insulin glargine and PZI.[50] Similar studies in diabetic cats have yet to be reported. In the author's experience, insulin glargine has a duration of effect ranging from 10 to 16 hours in most diabetic cats. The author has not yet encountered problems with inadequate absorption of insulin glargine, as described with Ultralente insulin, although it seems likely that this problem will be encountered as experience with this insulin analog accumulates. Currently, the author considers using insulin glargine when other insulin types are ineffective at controlling glycemia.

241.10.4 Storage and Dilution of Insulin

Freezing and heat inactivate insulin in the bottle. Although “room temperature” does not inactivate insulin, the author instructs owners to store insulin in the door of the refrigerator to maintain a consistent environment for the insulin preparation. Some veterinarians advocate replacing the insulin with a new bottle every month to avoid problems with loss of activity or sterility. The author has not appreciated a clinically significant loss of insulin action with time when insulin preparations are maintained in a constant environment (i.e., refrigerator) and handled appropriately. The author does not routinely recommend purchasing a new bottle of insulin every month, especially if the diabetic dog or cat is doing well. Loss of insulin activity in the bottle should always be considered whenever clinical signs recur, regardless of the amount of insulin in the bottle.

1576

1577

Dilution of insulin is a common practice, especially in cats and small dogs. Although studies evaluating the shelf-life of diluted insulin have not been published, the author recommends replacing diluted insulin preparations every 4 to 8 weeks. Even using these guidelines, insufficient amounts of insulin are administered when diluted insulin is used in some dogs and cats, despite appropriate dilution and insulin administration techniques; these inadequacies are corrected when full-strength insulin is used.

241.10.5 Initial Adjustments in Insulin Therapy

Diabetic dogs and cats require several days to equilibrate to changes in the insulin dosage or preparation. Therefore newly diagnosed diabetic dogs and cats are typically hospitalized for no more than 24 to 48 hours so that the diagnostic evaluation can be finished and insulin therapy begun. During hospitalization, blood glucose concentrations typically are determined at the time insulin is administered and at 11 AM, 2 PM, and 5 PM. The intent is to identify hypoglycemia (blood glucose concentration less than 80 mg/dL) in those dogs and cats that are unusually sensitive to the actions of insulin. If hypoglycemia occurs, the insulin dosage is decreased before the dog or cat is sent home. The insulin dosage is not adjusted in dogs and cats that remain hyperglycemic during these first few days of insulin therapy. The objective during this first visit is *not* to establish perfect glycemic control before sending the dog or cat home; rather, the objectives are to begin to reverse the metabolic derangements induced by the disease, to allow the dog or cat to equilibrate to the insulin and change in diet, to teach the owner how to administer insulin, and to give the owner a few days to become accustomed to treating the diabetic dog or cat at home. Adjustments in insulin therapy are made on subsequent evaluations, which typically occur once a week until an effective insulin treatment protocol has been identified.

241.10.6 Dietary Recommendations for Diabetic Dogs

Adjustments in diet and feeding practices should be directed at correcting or preventing obesity, maintaining consistency in the timing and caloric content of meals, and furnishing a diet that helps minimize the postprandial increase in the blood glucose concentration. Correcting obesity and increasing the fiber content of the diet are perhaps the two most beneficial steps that can be taken to improve control of glycemia. Obesity can cause impaired glucose tolerance in dogs and may be an important factor in the variation in response to insulin therapy. Weight reduction improves glucose tolerance in obese dogs, presumably by correcting obesity-induced insulin resistance. Successful weight reduction usually requires a combination approach involving restriction of caloric intake, the feeding of low-calorie dense diets, and an increase in caloric expenditure through exercise.

Diets containing an increased fiber content are beneficial for improving control of glycemia in diabetics.[51,52] The ability of the food fiber to form a viscous gel and thus impair convective transfer of glucose and water to the absorptive surface of the intestine appears to be of greatest importance in slowing intestinal glucose absorption. The more viscous soluble fibers (e.g., gums, pectin) slow glucose diffusion to a greater degree than do the less viscous insoluble fibers (e.g., lignin, cellulose) and as such are believed to be of greater benefit in improving control of glycemia. Most commercial high-fiber diets predominantly contain insoluble fiber, although diets containing mixtures of soluble and insoluble fiber are becoming available. The amount of fiber varies considerably among products, ranging from 3% to 25% of dry matter (normal diets contain less than 2% fiber on a dry matter basis). In general, diets containing 12% or more insoluble fiber or 8% or more of a mixture of soluble and insoluble fiber are most likely to be effective in improving glycemic control in diabetic dogs.

Common complications of feeding high-fiber diets include excessive frequency of defecation (insoluble fiber); constipation and obstipation (insoluble fiber); soft to watery stools (soluble fiber); excessive flatulence (soluble fiber); hypoglycemia 1 to 2 weeks after the increase in the fiber content of the diet; and refusal to eat the diet. If firm stools or constipation becomes a problem with diets high in insoluble fiber, a mixture of insoluble and soluble fiber diets can be fed, or soluble fiber (e.g., psyllium, canned pumpkin) can be added to the diet to soften the stool. Alternatively, if soft or watery diarrhea or flatulence becomes a problem with diets containing soluble fiber, an insoluble fiber diet can be added and the quantity of the soluble fiber diet decreased. Problems with palatability are usually the result of too rapid a switch from the dog's usual diet to the high-fiber diet or of boredom after the fiber diet has been consumed for several months. Periodic changes in the types of high-fiber diets and mixtures of diets help alleviate the problem with boredom. High-fiber diets should not be fed to thin or emaciated diabetic dogs until control of glycemia has been established and a normal body weight attained using a higher calorie dense, lower fiber diet designed for maintenance.

241.10.7 Dietary Recommendations for Diabetic Cats

The general principles for dietary therapy are similar for dogs and cats. Correction of obesity and minimization of the diet's impact on the postprandial blood glucose concentration are especially important. Obesity is common in diabetic cats and results from excessive caloric intake, typically caused by free-choice feeding of dry cat food. Obesity causes reversible insulin resistance, which resolves as weight is lost.[26,28] Control of glycemia often improves and some diabetic cats may revert to a subclinical diabetic state after weight reduction. Unfortunately, correction of obesity is difficult in cats because it requires restriction of daily caloric intake with a minimal corresponding increase in caloric expenditure (i.e., exercise). Although several

diets are available that have been specifically formulated for weight reduction in cats, diets containing increased amounts of fiber or protein should be used in the diabetic cat for reasons discussed below.

During the past decade, high-fiber, moderately fat restricted diets (e.g., Prescription Diet w/d, Hill's Pet Products, Topeka, KS) have been recommended for diabetic cats based on studies that documented a significant improvement in glycemic control when diabetic cats consumed a canned insoluble fiber (cellulose) diet.[53] Recently, dietary recommendations for diabetic cats have come under scrutiny, in part because of the seemingly increasing prevalence of obesity, chronic pancreatitis, and inflammatory bowel disease in cats during the past decade. Cats are carnivores and as such have higher dietary protein requirements than omnivores such as humans and dogs.[54] The activity of hepatic enzymes responsible for the phosphorylation of glucose for subsequent storage or oxidation (glucokinase, hexokinase) and the conversion of glucose to glycogen for storage in the liver (glycogen synthetase) are lower in cats compared with that for carnivores with omnivorous dietary habits.[55] The low activity of these hepatic enzymes suggests that cats primarily use gluconeogenic amino acids and fat, rather than starch, in their diet for energy; it also suggests that diabetic cats may be predisposed to developing higher postprandial blood glucose concentrations after consumption of diets with a high carbohydrate load and vice versa. Two carbohydrate-restricted diets that have been recommended for diabetic cats are Purina DM (Ralston Purina, St. Louis, Missouri) and Science Diet Feline Growth (Hill's Pet Products, Topeka, KS).[56,57] Purina DM is a high-protein, low-carbohydrate, low-fiber diet, and Science Diet Growth is a high-fat, low-carbohydrate, low-fiber diet.

1577

1578

The central theme in dietary studies in diabetic cats has been restriction of carbohydrate absorption by the gastrointestinal tract, by inhibiting starch digestion (acarbose), inhibiting intestinal glucose absorption (fiber), or decreasing carbohydrate ingestion (low-carbohydrate diets). Intuitively, the most effective means of minimizing gastrointestinal absorption of carbohydrates in the diabetic cat is to feed diets that contain minimal amounts of carbohydrate. The beneficial role in the control of glycemia, if any, of the high protein or high fat content of current carbohydrate-restricted diets is not yet known. It is also not known what effect, if any, a high protein intake may have on the development of ketosis or diabetic nephropathy, the induction of satiety, or maintenance of a stable body weight. Similarly, it is not known what effect, if any, a high fat intake may have on the development of obesity, hepatic lipidosis, and chronic pancreatitis or the induction of insulin resistance and increased hepatic glucose production secondary to the generation of nonesterified fatty acids, beta hydroxybutyric acid, and hypertriglyceridemia, especially in older cats that may have decreased lipoprotein and hepatic lipase activity.[58–60] For now, all three diets are considered viable choices for the management of diabetes in cats. Which diet will be most beneficial at improving control of glycemia in any given diabetic cat is unpredictable. As such, the initial diet of choice is based on the veterinarian's personal preferences and experience. If palatability or adverse effects become an issue or if poor control of glycemia persists despite adjustments in insulin therapy, a switch to one of the other diets should be considered.

241.10.8 Exercise

Exercise plays an important role in the maintenance of glycemic control by helping to promote weight loss and by eliminating the insulin resistance induced by obesity. Exercise also exerts a glucose-lowering effect by increasing the absorption of insulin from its injection site, increasing blood flow (and therefore insulin delivery) to exercising muscles, stimulating translocation of glucose transporters in muscle cells, and increasing glucose effectiveness (i.e., the ability of hyperglycemia to promote glucose disposal at basal insulin concentrations).[61,62] The daily routine for diabetic dogs should include exercise, preferably at the same time each day. Strenuous and sporadic exercise can cause severe hypoglycemia and should be avoided. The insulin dose should be decreased in dogs subjected to sporadic, strenuous exercise on days of anticipated increased

exercise. The reduction in the insulin dose required to prevent hypoglycemia is variable and is determined by trial and error. The author recommends reducing the insulin dose by 50% initially and making further adjustments based on the occurrence of symptomatic hypoglycemia and the severity of polyuria and polydipsia that develop during the ensuing 24 to 48 hours. In addition, owners must be aware of the signs of hypoglycemia and must have a source of glucose readily available to give their dog should any of these signs develop.

241.10.9 Identification and Control of Concurrent Problems

Concurrent diseases and administration of insulin-antagonistic drugs are both commonly identified in the dog and cat with newly diagnosed diabetes mellitus.[63,64] Concurrent disease and insulin-antagonistic drugs can interfere with tissue responsiveness to insulin as a result of a decreased number of insulin receptors at the surface of the cell membrane, alterations in insulin receptor binding affinity, or impairment in one of several postreceptor steps responsible for the activation of glucose transport systems. Loss of tissue responsiveness results in insulin resistance, which may be mild and easily overcome by increasing the dosage of insulin, or may be severe, causing sustained and marked hyperglycemia regardless of the type and dosage of insulin administered. Some causes of insulin resistance are readily apparent at the time diabetes is diagnosed, such as obesity and the administration of insulin-antagonistic drugs (e.g., glucocorticoids). Other causes of insulin resistance may not be readily apparent, and identification of these causes may require an extensive diagnostic evaluation. In general, any concurrent inflammatory, infectious, hormonal, or neoplastic disorder can cause insulin resistance and can interfere with the effectiveness of insulin therapy. Identification and treatment of concurrent disease plays an integral role in the successful management of the diabetic dog and cat. A thorough history and physical examination and a complete diagnostic evaluation are imperative in the newly diagnosed diabetic dog or cat.

241.10.10 Oral Hypoglycemic Drugs

In the United States, five classes of oral hypoglycemic drugs have been approved for the treatment of NIDDM in human beings: sulfonylureas, meglitinides, biguanides, thiazolidinediones, and alpha-glucosidase inhibitors. These drugs work by stimulating pancreatic insulin secretion (sulfonylureas, meglitinides), by enhancing tissue sensitivity to insulin (biguanides, thiazolidinediones), or by slowing postprandial intestinal glucose absorption (alpha-glucosidase inhibitors).[65] Although controversial, chromium and vanadium are trace minerals that may also function as insulin sensitizers. Studies have documented the efficacy of sulfonylureas for treating diabetes in cats[4,66] and of alpha-glucosidase inhibitors for improving glycemic control in diabetic dogs (see below).[67,68] The pharmacokinetic properties of the insulin-sensitizing drugs metformin (a biguanide) and troglitazone (a thiazolidinedione) have been evaluated in healthy cats.[69,70] Unfortunately, in one study metformin was ineffective as a sole therapeutic agent in a small number of newly diagnosed diabetic cats and was discontinued in most because of progressively worsening clinical signs or the development of ketoacidosis.[71] The only cat that responded to metformin had a fasting serum insulin concentration greater than 20 μU/mL, a finding consistent with the concept that metformin as an insulin-sensitizing drug is effective only in the presence of adequate blood concentrations of insulin. Similarly, oral chromium picolinate was ineffective in improving control of glycemia in a group of insulin-treated diabetic dogs.[72] Studies evaluating the efficacy of thiazolidinediones for the treatment of diabetes in dogs or cats have yet to be reported.

241.10.10.1 Sulfonylureas

Glipizide and glyburide are the sulfonylureas most commonly used to treat NIDDM. The primary effect of these drugs is direct stimulation of insulin secretion from the pancreas.[73] Some pancreatic insulin secretory capability must exist for sulfonylureas to be effective in improving glycemic control. Sulfonylurea treatment is ineffective as the sole form of treatment for IDDM and has not been effective in diabetic dogs, presumably because of the high incidence of IDDM in this species. The clinical response to glipizide and glyburide treatment in diabetic cats is variable, ranging from excellent (i.e., blood glucose concentrations decreasing to less than 200 mg/dL) to a partial response (i.e., clinical improvement but failure to resolve hyperglycemia), to no response.[4,66] Presumably, the population of functioning beta cells dictates the clinical response; that is, variation from an absence of functioning beta cells (severe IDDM) to a near-normal population of beta cells (mild NIDDM) results in a response range of none to excellent. Cats with a partial response to glipizide have some functioning beta cells but not enough to reduce the blood glucose concentration to less than 200 mg/dL. These cats may have severe NIDDM or the early stages of IDDM.

1578 1579

No consistent parameters have been identified that allow the clinician to prospectively determine which cats will respond to glipizide or glyburide therapy. Identification of a high preprandial serum insulin concentration or an increase in the serum insulin concentration during an insulin secretagogue test supports a diagnosis of NIDDM, but failure to identify these changes does not rule out the potential for a beneficial response to glipizide or glyburide. Selection of diabetic cats for treatment with glipizide must rely heavily on the veterinarian's assessment of the cat's health, the severity of clinical signs, the presence or absence of ketoacidosis, other diabetic complications (e.g., peripheral neuropathy), and the owner's desires.

Currently, the author administers glipizide (Glucotrol; Pfizer, New York, NY) at a dosage of 2.5 mg per os twice a day in conjunction with a meal, to diabetic cats that are nonketotic and relatively healthy on physical examination (Figure 241-6). The history and complete physical examination findings; body weight and urine glucose/ketone measurements; and several blood glucose concentrations are evaluated 2 weeks after initiation of glipizide therapy. If adverse reactions (Table 241-3) have not occurred after 2 weeks of treatment, the glipizide dosage is increased to 5 mg twice a day and the cat is re-evaluated 2 weeks later. Therapy is continued as long as the cat is stable. If euglycemia or hypoglycemia develop, the glipizide dosage may be tapered or discontinued and blood glucose concentrations re-evaluated 1 week later to assess the need for the drug. If hyperglycemia recurs, the dosage is increased or glipizide is reinitiated at a reduced dosage in cats that previously developed hypoglycemia. Glipizide is discontinued and insulin therapy is initiated if clinical signs continue to worsen; if the cat becomes ill or develops ketoacidosis; if the blood glucose concentration remains greater than 300 mg/dL after 1 to 2 months of therapy; or if the owners become dissatisfied with the treatment. It is important to remember that stress-induced hyperglycemia can artificially elevate the results of blood glucose tests. Therefore, if an owner believes that the drug is effective but the blood glucose concentration remains greater than 300 mg/dL, assessment of the fructosamine or glycosylated hemoglobin level will distinguish the stressed cat from one that truly is not responding to the drug. In some cats, glipizide becomes ineffective weeks to months later, and exogenous insulin is ultimately required to control the diabetic state. Presumably, the transition from glipizide to insulin treatment is due to progression of the underlying pathophysiologic mechanisms (e.g., islet-specific amyloid deposition) responsible for the development of diabetes in the cat. The more rapid the rate of progression, the shorter the beneficial response to glipizide.

One theoretical adverse reaction of chronic glipizide therapy is accelerated loss of pancreatic beta cell function caused by glipizide-induced stimulation of amylin secretion and worsening islet amyloidosis. In a recent study using an induced model of diabetes in cats, mild to moderate islet amyloid deposition and moderate to severe islet vacuolar change were identified in three and one of four cats, respectively, that were treated with glipizide for 18 months and in one and three of four cats, respectively, that were treated with recombinant human NPH insulin for 18 months.[74] The results suggested that glipizide treatment could cause progressive amyloid deposition as a result of glipizide-induced insulin and amylin secretion. Does this mean that glipizide should not be used for the treatment of diabetes in cats? To answer this question, one has to look at the underlying reason for using this drug. Glipizide has no advantage over insulin therapy with regard to cost of treatment, time required to treat, efficacy of treatment, or frequency of re-evaluations by the veterinarian. However, glipizide gives many owners an initially more palatable option (i.e., pills versus injections) for the treatment of their newly diagnosed diabetic cat. Most owners who are unwilling to give insulin injections would euthanize their cat. Many of these people are willing to try oral medication. During the ensuing weeks, many of these owners become willing to try insulin injections if glipizide therapy fails. In the author's opinion, the real advantage of glipizide is that it keeps more diabetic cats alive by giving the owner treatment options in lieu of insulin injections and by not forcing a quick life-and-death decision at the time diabetes is diagnosed.

241.10.11 Alpha-Glucosidase Inhibitors

Acarbose and miglitol are complex oligosaccharides of microbial origin that competitively inhibit alpha-glucosidases (glucoamylase, sucrase, maltase, and isomaltase) in the brush border of the small intestinal mucosa. Inhibition of these enzymes delays digestion of complex carbohydrates and disaccharides to monosaccharides. This inhibition delays absorption of glucose from the intestinal tract and decreases postprandial blood glucose concentrations. Placebo-controlled clinical studies in healthy dogs documented a decrease in postprandial glucose absorption and insulin secretion when the dogs were treated with acarbose, compared with placebo. A decrease in the daily insulin dose and the blood glucose and glycated protein concentrations were documented in diabetic dogs treated with acarbose, compared with placebo.[67,68] Unfortunately, diarrhea and weight loss as a result of carbohydrate malassimilation were common adverse effects, occurring in approximately 35% of dogs. Diarrhea was more prevalent at higher doses of acarbose (i.e., 100 and 200 mg/dog) and typically resolved within 2 to 3 days of discontinuation of the medication. Because of the cost and prevalence of adverse effects, acarbose should be reserved for treatment of poorly controlled diabetic dogs in which the cause of the poor control of glycemia cannot be identified and insulin treatment by itself is ineffective at preventing clinical signs of diabetes. The initial acarbose dosage is 12.5 to 25 mg per dog at each meal. The benefit of this drug depends on its interaction with the meal; it should be given only at the time of feeding. A stepwise increase to 50 mg/dog and, in large dogs (greater than 25 kg), a further increase to 100 mg/dog can be considered in dogs that fail to show improvement in control of glycemia after 2 weeks on the 12.5 to 25 mg/meal regimen. Adverse reactions (especially diarrhea) are more likely to occur at these higher doses.

241.11 TECHNIQUES FOR MONITORING DIABETIC CONTROL

The basic objective of therapy is to eliminate the clinical signs of diabetes mellitus while avoiding the common complications associated with the disease. Common complications in dogs and cats include blindness caused by cataract formation (dogs); weakness, ataxia, and a plantigrade stance caused by peripheral neuropathy (cats); poor haircoat from lack of grooming (cats); weight loss; hypoglycemia; recurring ketosis; and poor control of

glycemia secondary to concurrent infection, inflammation, neoplasia, or hormonal disorders (see Box 241-5). The devastating chronic complications of human diabetes (e.g., nephropathy, vasculopathy, coronary artery disease) require several decades to develop and are uncommon in diabetic dogs and cats; as such, it is not necessary to establish near-normal blood glucose concentrations in these animals. Most owners are happy and most dogs and cats are healthy and relatively asymptomatic if most blood glucose concentrations are kept between 100 and 250 mg/dL.

1579

1580

1580

Table • 241-3 Adverse Reactions to Glipizide Treatment in Diabetic Cats

ADVERSE REACTION	RECOMMENDATION
Vomiting within 1 hour of administration	Vomiting usually subsides after 2 to 5 days of glipizide therapy; decrease dose or frequency of administration if vomiting is severe; discontinue if vomiting persists longer than 1 week.
Increased serum hepatic enzyme activities	Continue treatment and monitor enzymes every 1 to 2 weeks initially; discontinue glipizide if cat becomes ill(lethargy, inappetence, vomiting) or if alanine transaminase activity exceeds 500 IU/L.
Icterus	Discontinue glipizide treatment; reinstitute glipizide treatment at lower dose and frequency of administration once icterus resolves (usually within 2 weeks); discontinue treatment permanently if icterus recurs.
Hypoglycemia	Discontinue glipizide treatment; recheck blood glucose concentration in 1 week; reinstitute glipizide therapy lower dose or frequency of administration if hyperglycemia recurs.

An important factor that affects the monitoring of diabetic cats more commonly than that of diabetic dogs is the propensity to develop stress-induced hyperglycemia as a result of frequent visits to the veterinary hospital for blood sampling. Once stress-induced hyperglycemia develops, it seems to be a perpetual problem, and blood glucose measurements can no longer be considered accurate. Veterinarians must remain wary of stress hyperglycemia in diabetic cats and should take steps to prevent its development. Micromanagement of diabetic cats should be avoided, and serial blood glucose curves should be done only when there is a perceived need to change insulin therapy. The determination of good versus poor control of glycemia should be based on the owner's subjective opinion regarding the presence and severity of clinical signs and the pet's overall health; the cat's ability to jump and its grooming behavior; the findings on physical examination, and the stability of body weight. Generation of a serial blood glucose curve should be reserved for newly diagnosed and poorly controlled diabetic cats unless stress-induced hyperglycemia is suspected. If this phenomenon is suspected, a switch should be made from reliance on serial blood glucose curves generated in the veterinary hospital to reliance on blood glucose results generated by the owner in the less-stressful home environment or on evaluation of sequential serum fructosamine concentrations, in addition to the history and physical examination findings.

241.11.1 History and Physical Examination

The most important initial parameters that should be assessed in the evaluation of control of glycemia are the owner's subjective opinion of the severity of clinical signs and the pet's overall health, the physical examination findings, and the stability of body weight. If the owner is happy with the results of treatment, if the physical examination is supportive of good glycemic control, and if the body weight is stable, the diabetic dog or cat is usually adequately controlled. Measurement of the serum fructosamine concentration can add further objective evidence of the status of glycemic control (see below). Poor control of glycemia should be suspected and additional diagnostics (i.e., serial blood glucose curve, serum fructosamine concentration, tests for concurrent disorders) or a change in insulin therapy should be considered if the owner reports clinical signs suggestive of hyperglycemia or hypoglycemia (i.e., polyuria, polydipsia, lethargy, weakness, ataxia) or peripheral neuropathy (changes in jumping ability, weakness, ataxia, plantigrade stance); if the physical examination identifies problems consistent with poor control of glycemia (e.g., thin or emaciated appearance, poor haircoat); or if the dog or cat is losing weight.[75]

Documentation of an increased blood glucose concentration does not *by itself* confirm poor control of glycemia. Stress or excitement can cause marked hyperglycemia that does not reflect the cat's or dog's responsiveness to insulin and can lead to the erroneous belief that the diabetic dog or cat is poorly controlled. If a discrepancy exists among the history, physical examination findings, and blood glucose concentration or if the cat or dog is fractious, aggressive, excited, or scared and the blood glucose concentration is known to be unreliable, the serum fructosamine concentration should be measured to further evaluate the status of glycemic control.

241.11.2 Serum Fructosamine Concentration

Fructosamines are glycated proteins synthesized after an irreversible, nonenzymatic, insulin-independent binding of glucose to serum proteins. Serum fructosamine concentrations are a marker of the mean blood glucose concentration during the circulating life span of the protein, which varies from 1 to 3 weeks, depending on the particular protein. The extent of glycosylation of serum proteins is directly related to the blood glucose concentration; the higher the average blood glucose concentration during the preceding 2 to 3 weeks, the higher the serum fructosamine concentration and vice versa. Serum fructosamine concentrations increase when glycemic control of the diabetic dog or cat worsens and decrease when glycemic control improves. The erum fructosamine concentration is not affected by acute increases in the blood glucose concentration, as occurs with stress or excitement-induced hyperglycemia, but it can be affected by hypoalbuminemia (less than 2.5 g/dL) and hyperlipidemia (triglycerides greater than 150 mg/dL).[39,76,77]

Fructosamine is measured in serum, which should be frozen and shipped on cold packs overnight to the diagnostic laboratory. In the author's laboratory, the normal reference ranges for serum fructosamine are 225 to 365 µmol/L in dogs and 190 to 365 µmol/L in cats.[39,78] Interpretation of the serum fructosamine level in a diabetic dog or cat must take into consideration the fact that hyperglycemia is common, even in well-controlled diabetic dogs and cats (Table 241-4). Most owners are happy with their pet's response to insulin treatment if the serum fructosamine concentration can be kept between 350 and 450 µmol/L. Values greater than 500 µmol/L suggest inadequate control of the diabetic state, and values greater than 600 µmol/L indicate serious lack of glycemic control. Serum fructosamine concentrations in the lower half of the normal reference range (i.e., less than 300 µmol/L) or below the normal reference range should raise concern that significant periods of hypoglycemia have occurred. Increased serum fructosamine concentrations (i.e., greater than 500 µmol/L) suggest poor control of glycemia and a need for insulin adjustment but do not identify the underlying problem.

Table • 241-4 Sample Handling, Methodology, and Normal Values for Serum Fructosamine Concentrations Measured in Our Laboratory in Dogs and Cats

Blood sample	1 to 2 mL serum
Sample handling	Freeze until assayed
Methodology	Automated colorimetric assay using nitroblue tetrazolium chloride
Factors affecting results	Hypoproteinemia and hypoalbuminemia (decreased), hyperlipidemia (decreased [dog]), azotemia (decreased [dog]), storage at room temperature (decreased)
Normal range	Dog: 225 to 365 µmol/L Cat: 190 to 365 µmol/L
Interpretation in diabetic dogs and cats	
Excellent control	350 to 400 µmol/L
Good control	400 to 450 µmol/L
Fair control	450 to 500 µmol/L
Poor control	>500 µmol/L
Prolonged hypoglycemia	<300 µmol/L

241.11.3 Urine Glucose Monitoring

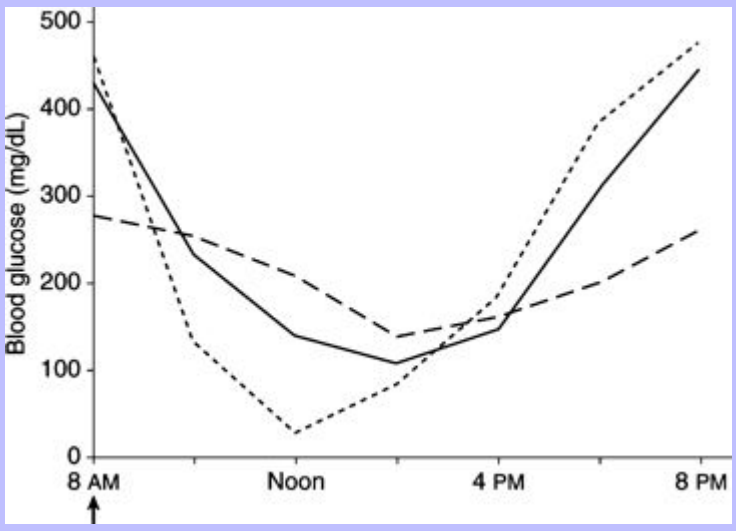
In diabetic dogs and cats that have problems with recurring ketosis or hypoglycemia, occasional monitoring of urine for glycosuria and ketonuria in the home environment is helpful for (1) determining whether ketonuria or persistent negative glycosuria, respectively, is present; (2) in cats that have reverted to a non-insulin-requiring diabetic state, for determining whether glycosuria has recurred; (3) in cats treated with oral hypoglycemic drugs, for determining whether glycosuria has improved or worsened; and (4) in cats with suspected stress-induced hyperglycemia, for differentiating transient from persistent hyperglycemia. For cats, a small amount of urine can be obtained by decreasing the amount of litter in the pan; by temporarily replacing the litter with nonabsorbable material, such as aquarium gravel; or by assessing the change in the color of urine glucose test squares (Glucotest Feline Urinary Glucose Detection System; Ralston Purina) that have been mixed into the kitty litter. We do not have the owner adjust daily insulin dosages based on morning urine glucose measurements in dogs except to decrease the insulin dose in dogs with recurring hypoglycemia and persistent negative glycosuria. In the author's experience, the vast majority of diabetic dogs develop complications as a result of owners being misled by morning urine glucose concentrations. For both dogs and cats, persistent glycosuria throughout the day and night suggests inadequate control of the diabetic state and the need for a more complete evaluation of diabetic control using techniques discussed in this section.

241.11.4 Serial Blood Glucose Curve

If an adjustment in insulin therapy is deemed necessary after a review of the history, physical examination findings, changes in body weight, and serum fructosamine concentration, a serial blood glucose curve should be generated to provide guidance for the adjustment, unless the blood glucose measurements are unreliable because of stress, aggression, or excitement. The serial blood glucose curve provides guidelines for rational adjustments in insulin therapy. Evaluation of a serial blood glucose curve is mandatory during the initial regulation of the diabetic dog or cat and is necessary in the dog or cat in which clinical manifestations of hyperglycemia or hypoglycemia have developed. Reliance on the history, physical examination findings, body weight, and serum fructosamine concentration to determine when a blood glucose curve is needed helps reduce the number of blood glucose curves generated and the number of venipunctures and also shortens the

time the dog or cat spends in the hospital. This may minimize the animal's aversion to evaluations and may improve the chance of obtaining meaningful results when a blood glucose curve is needed.

Figure 241-7 Blood glucose concentration curves in a dachshund receiving 0.8 U of recombinant human Lente insulin per kilogram of body weight twice a day *(solid line);* a miniature poodle receiving 0.6 U of recombinant human Lente insulin per kilogram of body weight twice a day *(broken line);* and a terrier-mix receiving 1.1 U of recombinant human Lente insulin per kilogram of body weight twice a day *(dotted line)*. Insulin and food were given at 8 AM. Interpretation of the blood glucose curves suggests a short duration of insulin effect in the dachshund, insulin underdosage in the miniature poodle, and the Somogyi effect in the terrier-mix. Note that the blood glucose concentrations were similar in the three dogs at 2 PM and 4 PM and that the glucose results at these times do not establish the diagnosis in any of the dogs. (From Nelson RW, Couto CG: Small Animal Internal Medicine, 3rd ed. St Louis, Mosby, 2003, p 741.)

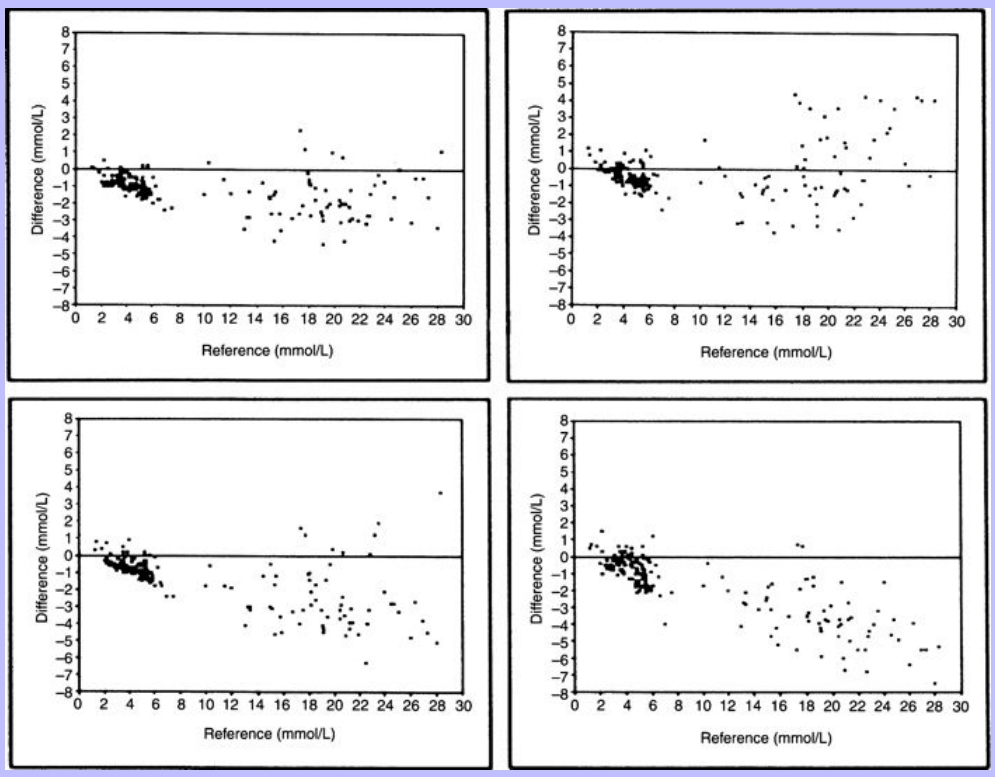


Blood glucose concentrations are typically determined with either a point-of-care glucose analyzer or a hand-held portable blood glucose monitoring device. Commercially available portable blood glucose monitoring devices provide blood glucose concentrations reasonably close to those obtained with reference methods, although the results often consistently overestimate or underestimate actual glucose values (Figure 241-8).[78,79] The blood glucose values determined by most portable blood glucose monitoring devices typically are lower than the actual glucose values determined by reference methods. This may result in an incorrect diagnosis of hypoglycemia or the misperception that glycemic control is better than it actually is. Failure to

consider this “error” could result in insulin underdosage and the potential for persistence of clinical signs despite apparently “acceptable” blood glucose results.

The author prefers to adjust insulin therapy based on interpretation of a single serial blood glucose curve, with the ideal goal of maintaining the blood glucose concentration between 100 and 250 mg/dL. We typically relies on owner perceptions of clinical response and the change in the serum fructosamine concentration to initially assess the impact of the insulin adjustment on control of glycemia. If problems persist, we consider repeating the blood glucose curve. We rarely perform blood glucose curves on multiple consecutive days because it promotes stress-induced hyperglycemia. In addition, information gained from a prior serial blood glucose curve should never be assumed to be reproducible on subsequent curves. Variables such as the actual amount of insulin drawn into the syringe and subsequently absorbed from the subcutaneous site of deposition and the interaction among insulin, diet, exercise, stress, excitement, any concurrent disorders, and secretion of the counter-regulatory hormones (i.e., glucagon, epinephrine, cortisol, growth hormone) change with time and affect the reproducibility of serial blood glucose curves. Lack of consistency in the results of serial blood glucose curves creates frustration for many veterinarians. It is important to remember that this lack of consistency is a direct reflection of all the variables that affect the blood glucose concentration in diabetics. Daily self-monitoring of blood glucose concentrations and daily adjustments in the insulin dose are recommended in human diabetics to minimize the effect of these variables on control of glycemia. A similar approach for diabetic dogs and cats undoubtedly will become more common in the future, as home glucose monitoring techniques are refined. For now, initial assessment of the control of glycemia is based on the owners' perception of their diabetic pet's health combined with periodic examinations by the veterinarian. Serial blood glucose measurements are indicated if poor control of glycemia is suspected. The purpose of serial blood glucose measurements is to obtain a glimpse at the actions of insulin in that diabetic animal and hopefully to identify a reason that could explain why the diabetic dog or cat is poorly controlled.

Figure 241-8 Scatterplots of the difference between blood glucose concentrations obtained with four portable blood glucose meters and concentrations obtained with a reference method versus concentration obtained with the reference method for blood samples from 170 dogs. (From Wess G, Reusch C: Evaluation of five portable blood glucose meters for use in dogs. J Am Vet Med Assoc 216:203, 2000.)



241.11.5 Generation of the Serial Blood Glucose Curve at Home

An alternative to hospital-generated blood glucose curves for cats is to have the owner generate the blood glucose curve at home using the marginal ear vein prick technique and a portable home blood glucose monitoring device that allows the owner to touch the drop of blood on the ear with the end of the glucose test strip (e.g., Glucometer Elite XL portable blood glucose meter; Bayer Diagnostics, Tarrytown, New York) (Figure 241-9). The marginal ear vein prick technique decreases the need for physical restraint during sample collection, thereby minimizing the cat's discomfort and stress. The accuracy of blood glucose results are similar when blood for glucose determination is obtained by ear prick and venipuncture.[79,80] However, blood glucose results obtained by portable blood glucose monitoring devices may overestimate or, more commonly, underestimate the actual blood glucose values obtained with reference methods, as discussed in the previous

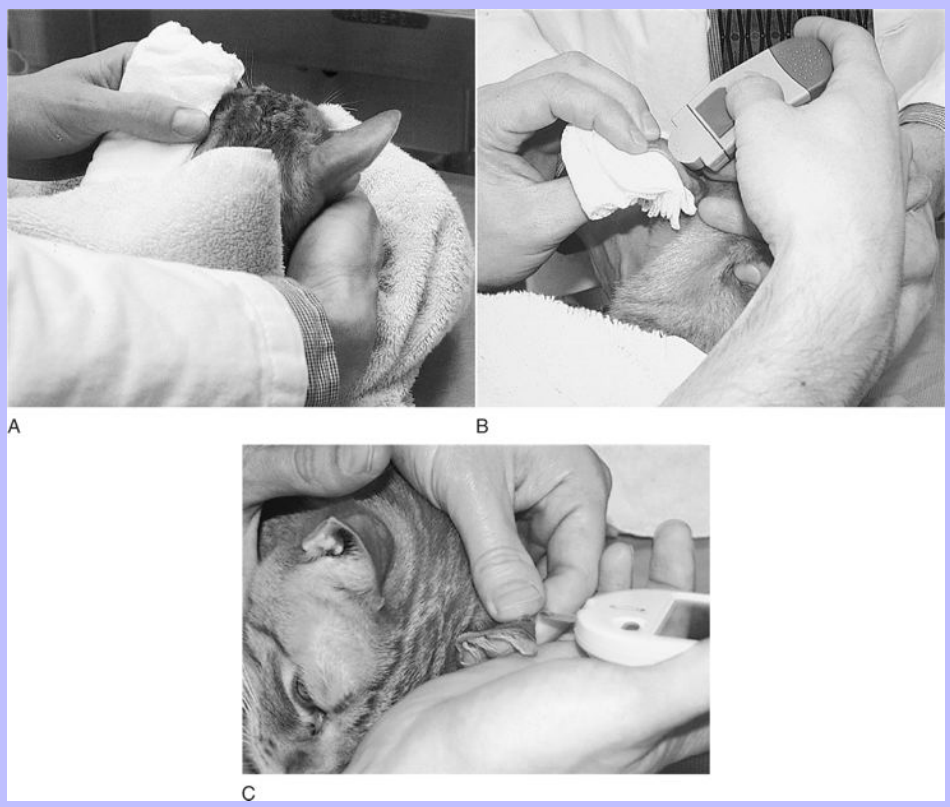
1583
1584

section.[81] This inherent error must be considered in the interpretation of blood glucose results obtained by a portable home blood glucose monitoring device. Several web sites on the Internet (e.g., www.sugarcats.net/sites/harry/) explain in detail the marginal ear vein prick technique in lay terms and provide information on owner experiences with the technique and with different portable home blood glucose meters. At the time diabetes is diagnosed, the author provides this web site URL to clients and asks them to read the information to decide if they would be interested in monitoring blood glucose concentrations at home. We spend time teaching the technique to individuals willing to give it a try, advise them on how often to perform a blood glucose curve (ideally no more frequently than one day every 2 to 4 weeks), and how often to measure the blood glucose concentration on the day of the curve (typically at the time of insulin administration and 3, 6, 9, and 12 hours later). We have had excellent results using the marginal ear vein prick technique in cats. Stress has been significantly reduced, and the reliability of the blood glucose results has improved immensely. The biggest problem has been overzealous owners who monitor blood glucose concentrations too frequently. A similar approach can be used in diabetic dogs, using either the ear or lip prick technique. However, the author does not push home glucose monitoring for dogs as much as for cats, primarily because stress-induced hyperglycemia is not as significant a problem in diabetic dogs.

1584

1585

Figure 241-9 Marginal ear vein prick technique for measuring the blood glucose concentration. **A,** A hot washcloth is applied to the pinna for 2 to 3 minutes to increase circulation to the ear **B,** The marginal ear vein is identified on the periphery of the outer side of the pinna, and a thin coating of petrolatum jelly is applied to a small spot over the vein; the spot is then pricked with the lancet device supplied with the portable blood glucose meter. Gauze should be placed between the pinna and the digit holding the pinna to prevent pricking of the finger if the lancet's blade accidentally passes through the pinna. Petrolatum jelly is applied to help the blood form a ball on the pinna as it seeps from the lanced site. **C,** Digital pressure is applied in the area of the lanced skin to promote bleeding. The glucose test strip is touched to the drop of capillary blood that forms and is removed once enough blood has been drawn into the test strip to activate the meter. (From Nelson RW, Couto CG: Small Animal Internal Medicine, 3rd ed. St Louis, Mosby, 2003, p 759.)



For the marginal ear vein prick technique, the cat is allowed to remain in sternal recumbency with restraint only as needed to keep the animal stationary. The marginal ear vein is identified, and a damp cloth or gauze sponge previously warmed in water is applied to the vein for 15 to 30 seconds to increase perfusion. A thin film of petrolatum is placed over the sampling site to allow a drop of blood to form without dissipating into the fur, the pinna is immobilized with a digit, an automatic lancing device (e.g., Microlet automatic lancing device; Bayer Diagnostics) is placed over the vein, the ejected needle is used to nick the ear vein and, if necessary, the pinna in the region of the nick site is gently squeezed to promote formation of a drop of blood. A glucose test strip previously inserted into the blood glucose meter is applied to the drop of blood to measure the blood glucose concentration (see Figure 241-9). Digital pressure is then applied at the marginal ear vein prick site until bleeding stops. The skin puncture is rarely painful, and the puncture sites are barely visible even after numerous blood collections. Application of a thin film of petrolatum is critical for formation of the drop of blood. A small amount of padding, such as a cotton ball or gauze sponge, between the pinna and the digit used to stabilize the pinna helps prevent inadvertent pricking of the finger if the lancet goes through the pinna. Dehydration can interfere with the ability to obtain a drop of blood; a problem that occurs in some poorly controlled cats with marked hyperglycemia and severe polyuria and polydipsia. Administration of subcutaneous fluids may improve circulation to the ear. Only portable home blood glucose monitoring devices that allow the end of the glucose test strip to touch the drop of blood formed on the pinna while the strip is in the glucose monitoring device are used.

241.11.6 Evaluation of Aggressive, Excitable, or Stressed Diabetic Cats or Dogs

Hyperglycemia induced by stress, aggression, or excitement is the single biggest problem that affects the accuracy of the serial blood glucose curve. Stress can over-ride the glucose-lowering effect of the insulin injection, causing high blood glucose concentrations despite the presence of adequate amounts of insulin in the circulation, leading to a spiraling path of insulin overdosage, hypoglycemia, Somogyi phenomenon, and poor control of glycemia. The primary factors that induce stress hyperglycemia are hospitalization and multiple venipunctures. An alternative to hospital-generated blood glucose curves is to have the owner generate the blood glucose curve at home, as discussed above. Alternatively, serum fructosamine concentrations can be used to assess control of glycemia and the effectiveness of adjustments in insulin therapy in aggressive, excitable, or stressed diabetic cats or dogs. If a change in insulin therapy is deemed necessary, the clinician must make an educated guess as to where the problem lies (e.g., low insulin dose, short duration of insulin effect), adjust the insulin dose, and rely on the change in subsequent serum fructosamine measurements to assess the benefit of the change. The author measures serum fructosamine concentrations prior to and 2 to 3 weeks after changing insulin therapy. If the change has improved control of glycemia, the serum fructosamine concentration should decrease. If the serum fructosamine concentration is the same or has increased, the change was ineffective at improving glycemic control, another change in therapy can be tried, and the serum fructosamine measured again 2 to 3 weeks later.

241.12 COMPLICATIONS OF INSULIN THERAPY

241.12.1 Hypoglycemia

Hypoglycemia is a common complication of insulin therapy and is most apt to occur after sudden large increases in the insulin dose; with excessive overlap of insulin action in dogs and cats receiving insulin twice a day; during unusually strenuous exercise (dogs); after prolonged inappetence; after sudden decreases in insulin resistance; and in insulin-treated cats that have reverted to a non-insulin-dependent state. In these situations severe hypoglycemia may occur before glucose counter-regulation (i.e., secretion of glucagon, epinephrine,

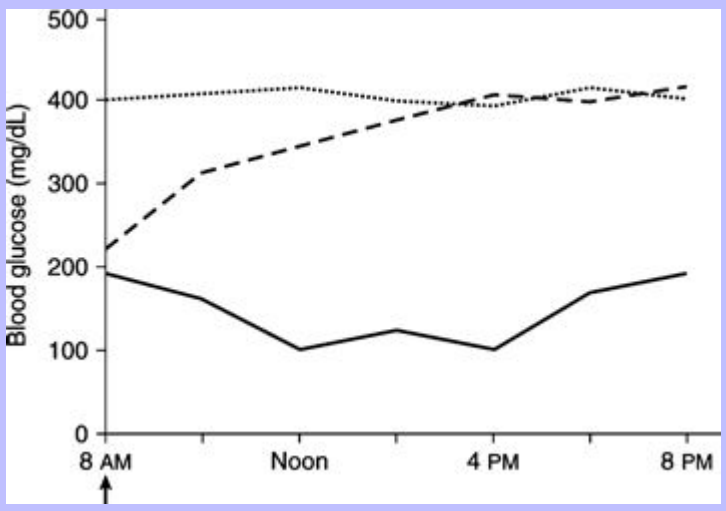
cortisol, and growth hormone) is able to compensate for and reverse the hypoglycemia. Signs of hypoglycemia include lethargy, weakness, head tilting, ataxia, seizures, and coma. The occurrence and severity of clinical signs depends on the rate of blood glucose decline and the severity of hypoglycemia. Symptomatic hypoglycemia is treated with glucose administered as food, sugar water, or intravenous dextrose. Whenever signs of hypoglycemia occur, the owner should be instructed to stop insulin therapy until glycosuria recurs. The adjustment in the subsequent insulin dosage is somewhat arbitrary; as a general rule, the insulin dosage initially should be reduced 25% to 50%, and subsequent adjustments in the dosage should be based on clinical response and blood glucose measurements. Failure of glycosuria to recur after a hypoglycemic episode suggests reversion to a non-insulin-dependent diabetic state or impaired glucose counter-regulation.

241.12.2 Stress Hyperglycemia

Transient hyperglycemia is a well-recognized problem in fractious or frightened cats. Hyperglycemia develops as a result of an increase in catecholamines and, in struggling cats, lactate concentrations and presumably increased hepatic glucose production.[82,83] Blood glucose concentrations typically exceed 200 mg/dL in these cats, and values in excess of 300 mg/dL are common. Diabetes mellitus may be inadvertently diagnosed in such cats if the diagnosis is based solely on the blood glucose concentration. Stress hyperglycemia can also significantly increase blood glucose concentrations in diabetic cats despite administration of insulin, an effect that seriously interferes with the clinician's ability to judge the effectiveness of exogenous insulin accurately. Induction of stress hyperglycemia is variable but usually starts during a venipuncture procedure and begins earlier and earlier on subsequent visits to the veterinarian, until eventually stress hyperglycemia is induced by hospitalization and ultimately by the car ride to the veterinary hospital. Blood glucose concentrations can remain greater than 400 mg/dL throughout the day, despite administration of insulin (Figure 241-10), when stress hyperglycemia develops prior to the first venipuncture of the day. Failure to recognize the effect of stress on blood glucose measurements may lead to the erroneous perception that the diabetic cat is poorly controlled, and insulin therapy is invariably adjusted, often by increasing the insulin dosage; repetition of this cycle eventually culminates in the Somogyi phenomenon, clinically apparent hypoglycemia, or referral for evaluation of insulin resistance.

Stress hyperglycemia should be suspected if the cat is visibly upset or aggressive or struggles during restraint and the venipuncture process. However, stress hyperglycemia can also be present in diabetic cats that are easily removed from the cage and do not resist the blood sampling procedure. These cats are scared, but rather than become aggressive, they remain crouched in the back of the cage, often have dilated pupils, and usually are flaccid when handled. Stress hyperglycemia should also be suspected when (1) a disparity exists between assessment of glycemic control based on the results of the history, physical examination, and stability of body weight and assessment of glycemic control based on the results of blood glucose measurements, or (2) the initial blood glucose concentration measured in the morning is in an acceptable range (i.e., 150 to 250 mg/dL), but subsequent blood glucose concentrations increase steadily throughout the day (see Figure 241-10). Once stress hyperglycemia develops, it is usually a perpetual problem, and blood glucose measurements can no longer be considered accurate.

Figure 241-10 Blood glucose curves in a 5.3 kg male cat receiving 2 U of recombinant human Ultralente insulin *(solid line-solid circles)* 2 weeks after initiation of insulin therapy; 2 U of recombinant human Ultralente insulin *(broken line)* 2 months later; and 6 U of recombinant human Ultralente insulin *(dotted line)* 4 months later. The insulin dosage had been gradually increased based on the blood glucose curve results. The owner reported minimal clinical signs regardless of the insulin dosage, the cat had maintained its body weight, and the blood glycosylated hemoglobin concentration was 2.2% at the 4-month recheck. The cat became progressively more fractious during each hospitalization, supporting a finding of stress-induced hyperglycemia as the reason for the discrepancy between the blood glucose values and other parameters used to evaluate glycemic control. ↑, Subcutaneous insulin injection and food. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 3rd ed. Philadelphia, WB Saunders, 2004, p 569.)



241.12.3 Recurrence or Persistence of Clinical Signs

Recurrence or persistence of clinical signs of diabetes is the most common “complication” of insulin therapy in diabetic dogs and cats. Recurrence or continuing clinical signs suggest insulin ineffectiveness, which is usually caused by problems with the biologic activity of the insulin or by owner technique in administering the insulin; problems with the insulin treatment regimen; or problems with responsiveness to insulin caused by

concurrent inflammatory, infectious, neoplastic, or hormonal disorders (i.e., insulin resistance). The most common problems with the insulin treatment regimen in the dog are insulin underdosage, the Somogyi phenomenon, short duration of effect of Lente insulin, and once a day insulin administration. The most common problems with the insulin treatment regimen in the cat are insulin overdosage, causing the Somogyi phenomenon; inadequate absorption of longer acting insulin preparations; short duration of effect of intermediate-acting insulin preparations; and once a day insulin administration.

Discrepancies in the parameters used to assess glycemic control, resulting in an erroneous belief that the diabetic dog or cat is poorly controlled, should also be considered. This situation usually is caused by erroneously high blood glucose concentrations that suggest insulin ineffectiveness; these high values may be stress induced and do not reflect the animal's responsiveness to insulin. In the evaluation of a diabetic dog or cat for suspected insulin ineffectiveness, it is important that all parameters used to assess glycemic control be critically analyzed, most notably the owner's perception of how the pet is doing in the home environment, physical examination findings, and changes in body weight. If the history, physical examination, change in body weight, and serum fructosamine concentration suggest poor control of the diabetic state, a diagnostic evaluation to identify the cause is warranted, beginning with evaluation of the owner's insulin administration technique and the biologic activity of the insulin preparation.

241.12.3.1 Insulin Underdosage

Control of glycemia can be established in most dogs and cats using less than 1 U of insulin per kilogram of body weight administered twice each day. An inadequate insulin dosage in conjunction with once a day insulin therapy is a common cause of persistence of clinical signs. In general, insulin underdosage should be considered if the insulin dosage is less than 1 U/kg and the dog or cat is receiving insulin twice a day. If insulin underdosage is suspected, the insulin dose should be gradually increased by 1 to 5 U per injection in dogs (depending on the size of the dog) and 0.5 to 1 U per injection in cats, per week. The effectiveness of the change in therapy should be evaluated by the owner's perception of clinical response and measurement of serum fructosamine or serial blood glucose concentrations. Other causes of insulin ineffectiveness (most notably the Somogyi phenomenon) should be considered if the insulin dosage exceeds 1 to 1.5 U/kg/injection, if insulin is being administered every 12 hours, and if control of glycemia remains poor.

241.12.3.2 Insulin Overdosage and Glucose Counter-Regulation (Somogyi Phenomenon)

The Somogyi phenomenon results from a normal physiologic response to impending hypoglycemia induced by excessive insulin. When the blood glucose concentration declines to less than 65 mg/dL or when the blood glucose concentration decreases rapidly regardless of the glucose nadir, direct hypoglycemia-induced stimulation of hepatic glycogenolysis and secretion of diabetogenic hormones, most notably epinephrine and glucagon, increase the blood glucose concentration, minimize signs of hypoglycemia, and cause marked hyperglycemia within 12 hours of glucose counter-regulation (Figure 241-11). The marked hyperglycemia that occurs after hypoglycemia is due in part to inability of the diabetic dog or cat to secrete sufficient endogenous insulin to dampen the rising blood glucose concentration. By the next morning, the blood glucose concentration can be extremely elevated (400 to 800 mg/dL), and the morning urine glucose concentration is consistently 1 to 2 g/dL as measured with urine glucose test strips. Unrecognized short duration of insulin effect combined with insulin dosage adjustments based on morning urine glucose concentrations is historically the most common cause of the Somogyi phenomenon in dogs.

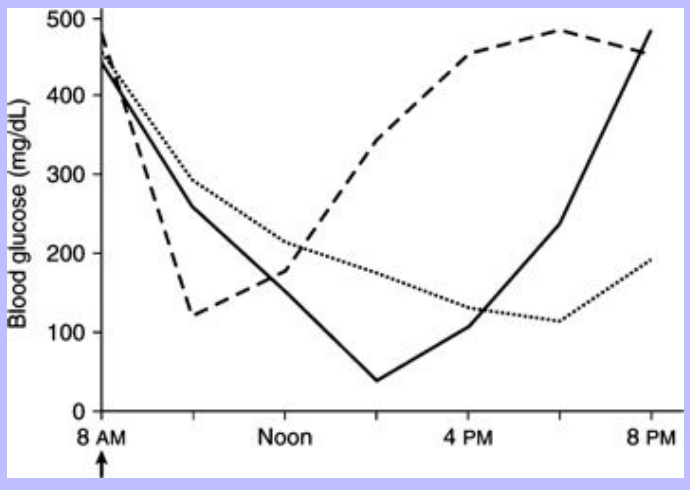
Clinical signs of hypoglycemia are typically mild or are not recognized by the owner; clinical signs caused by hyperglycemia tend to dominate the clinical picture. The insulin dose that induces the Somogyi

phenomenon is variable and unpredictable. The Somogyi phenomenon is often suspected in poorly controlled diabetic dogs for which the insulin dosage is approaching 2.2 U/kg/injection but can also occur at insulin dosages less than 0.5 U/kg/injection. Toy and miniature breeds of dogs are especially susceptible to development of the Somogyi phenomenon with lower than expected doses of insulin. In cats, the Somogyi phenomenon can be induced with insulin doses of 2 to 3 U per injection; as a result, cats may receive 10 to 15 U of insulin per injection because veterinarians, interpreting the persistence of clinical signs and the high blood glucose and serum fructosamine concentrations as underdosage, increase the insulin dose, thereby perpetuating the problem.

1586

1587

Figure 241-11 Blood glucose concentration curves from three dogs with poorly controlled diabetes that were treated with recombinant human Lente insulin twice a day, illustrating the typical blood glucose curves suggestive of the Somogyi phenomenon. In one dog *(solid line)*, the glucose nadir is less than 80 mg/dL and is followed by a rapid increase in the blood glucose concentration. In another dog *(dashed line)*, a rapid decrease in the blood glucose concentration occurs within 2 hours of insulin administration and is followed by a rapid increase in the blood glucose concentration; the rapid decrease in blood glucose stimulates glucose counter-regulation despite maintenance of the blood glucose nadir above 80 mg/dL. In the third dog *(dotted line)*, the blood glucose curve is not suggestive of the Somogyi phenomenon per se. However, the insulin injection causes the blood glucose level to decrease by approximately 300 mg/dL during the day, and the blood glucose concentration at the time of the evening insulin injection is considerably lower than the 8 AM blood glucose concentration. If a similar decrease in the blood glucose occurs with the evening insulin injection, hypoglycemia and the Somogyi phenomenon would occur at night and would explain the high blood glucose concentration in the morning and the poor control of the diabetic state. (From Nelson RW, Couto CG: Small Animal Internal Medicine, 3rd ed. St Louis, Mosby Inc, 2003, p 745.)



Diagnosis of the Somogyi phenomenon requires demonstration of hypoglycemia (a serum glucose concentration less than 80 mg/dL) followed by hyperglycemia (a serum glucose concentration greater than 300 mg/dL) after insulin administration. The Somogyi phenomenon should also be suspected when the blood glucose concentration decreases rapidly regardless of the glucose nadir (e.g., a drop from 400 to 100 mg/dL within 2 to 3 hours). If the duration of insulin effect is greater than 12 hours, hypoglycemia often occurs at night after the evening dose of insulin, and the serum glucose concentration is typically greater than 300 mg/dL the next morning (see Figure 241-11). Unfortunately, diagnosis of the Somogyi phenomenon can be elusive, partly because of the effects of the diabetogenic hormones on blood glucose concentrations after an episode of glucose counter-regulation. Secretion of diabetogenic hormones during the Somogyi phenomenon may induce insulin resistance, which can last 24 to 72 hours after the hypoglycemic episode. If a serial blood glucose curve is obtained on the day glucose counter-regulation occurs, hypoglycemia can be identified and the diagnosis established. However, if the serial blood glucose curve is obtained on a day when insulin resistance predominates, hypoglycemia will not be identified, and the insulin dose may be incorrectly increased in response to the high blood glucose values. A cyclic history of 1 or 2 days of good glycemic control followed by several days of poor control should raise suspicion for insulin resistance caused by glucose counter-regulation. Serum fructosamine concentrations are unpredictable but are usually increased (greater than 500 µmol/L); these results confirm poor glycemic control but do not identify the underlying cause.

Establishment of the diagnosis may require several days of hospitalization and serial blood glucose curves, an approach that eventually leads to problems with stress-induced hyperglycemia. An alternative approach, which the author prefers, is to arbitrarily reduce the insulin dosage 1 to 5 U and have the owner evaluate the dog's or cat's clinical response over the following 2 to 5 days. If clinical signs of diabetes worsen after a reduction in the insulin dosage, another cause of the insulin resistance should be pursued. However, if the owner reports no change or improvement in clinical signs, the clinician should continue to reduce the insulin dosage gradually. Alternatively, glycemic regulation of the diabetic dog or cat could be started over, using an insulin dosage of 0.25 U/kg (dogs) or 1 U/injection (cats) given twice daily.

241.12.3.3 Short Duration of Insulin Effect

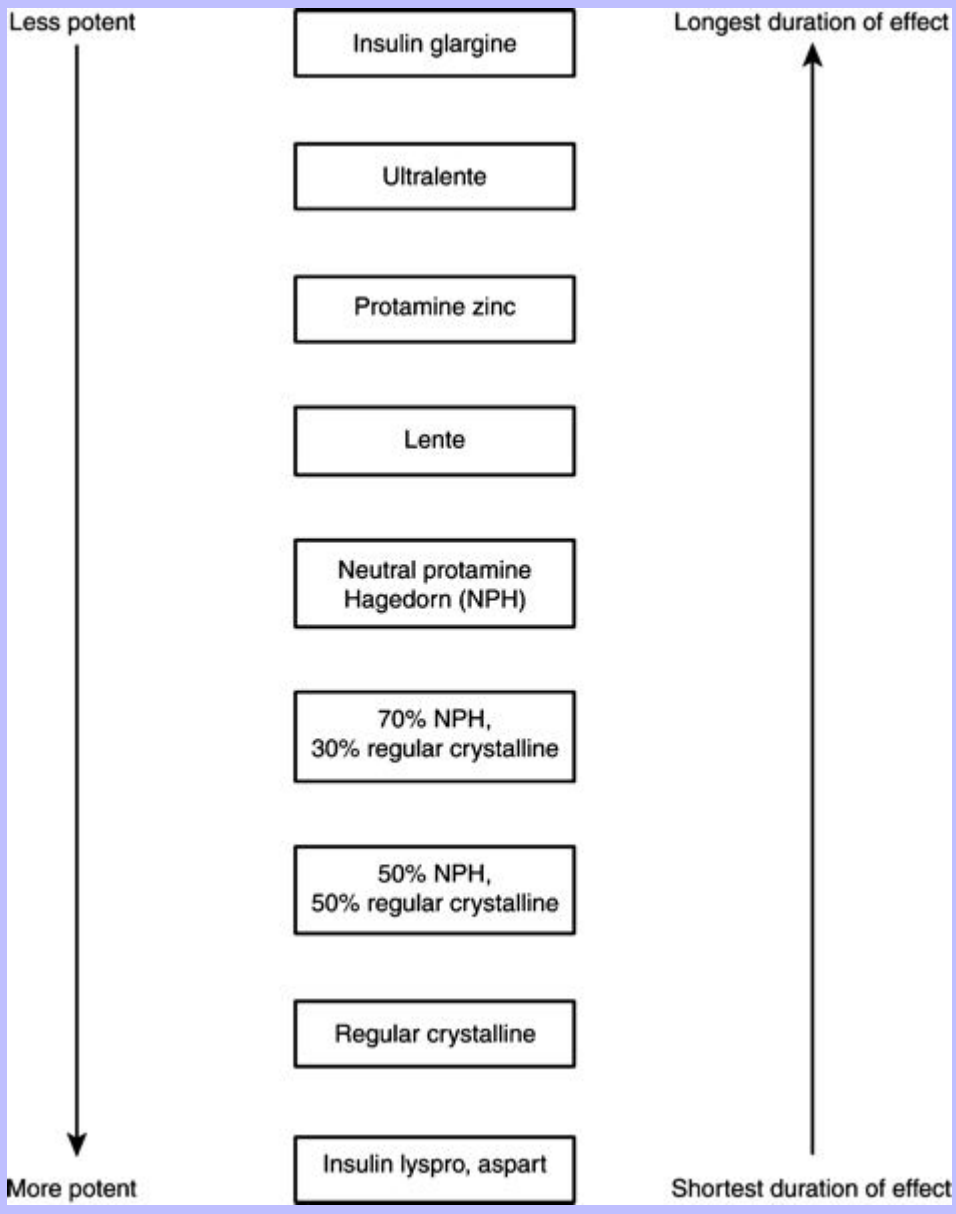
Short duration of insulin effect (i.e., less than 10 hours) is a common problem in diabetic dogs, and especially diabetic cats, despite twice a day insulin administration. In some diabetic cats, the duration of effect of NPH and Lente insulin is less than 8 hours. As a result, significant hyperglycemia (blood glucose concentration greater than 300 mg/dL) occurs for several hours each day, and the owners of these pets usually mention continuing problems with persistence of clinical signs or weight loss, or weakness caused by the development of peripheral neuropathy. Diabetic dogs with short duration of insulin have persistent morning glycosuria (greater than1 g/dL on urine glucose test strips). If the owners are adjusting the daily insulin dosage based on the morning urine glucose concentration, they usually induce the Somogyi phenomenon, because the insulin dosage is gradually increased in response to the persistent morning glycosuria. Serum fructosamine concentrations are variable but typically greater than 500 µmol/L. The diagnosis of short duration of insulin effect is made by demonstrating recurrence of hyperglycemia (blood glucose concentration greater than 250 mg/dL) within 6 to 10 hours of the insulin injection; also, the lowest blood glucose concentration is maintained above 80 mg/dL (see Figure 241-7). The clinician must evaluate multiple blood glucose concentrations obtained throughout the day to establish the diagnosis. The use of one or two afternoon blood glucose determinations consistently fails to identify the problem. Treatment involves changing to a longer acting insulin given twice a day (e.g., switching to PZI [cats], Ultralente, or

insulin glargine) or increasing the frequency of insulin administration (i.e., initiating three times a day therapy) if the duration of effect is less than 8 hours.

241.12.3.4 Prolonged Duration of Insulin Effect

In some diabetic dogs and cats, the duration of effect of Lente insulin or PZI is greater than 12 hours, and twice a day insulin administration creates problems with hypoglycemia and the Somogyi phenomenon. In these dogs and cats, the glucose nadir after morning administration of insulin typically occurs near the time of the evening insulin administration, and the morning blood glucose concentration is usually greater than 300 mg/dL (see Figure 241-11). Gradually decreasing blood glucose concentrations measured at the time of sequential insulin injections are another indication of prolonged duration of insulin effect. The effectiveness of insulin in lowering the blood glucose concentration varies from day to day, presumably because of varying concentrations of diabetogenic hormones, the secretion of which was induced by prior hypoglycemia. Serum fructosamine concentrations are variable but typically greater than 500 μmol/L. Effective treatment depends in part on the duration of effect of the insulin. A 24-hour blood glucose curve should be generated after administration of insulin once in the morning and with the dog or cat being fed at the usual times of the day. This allows the clinician to estimate the duration of effect of the insulin. If the duration of effect is less than 16 hours, a shorter acting insulin given twice a day or a lower dose of the same insulin given in the evening, compared with the morning insulin dose, can be tried. If the duration of effect is 16 hours or longer, switching to a longer acting insulin administered once a day or administering Lente insulin in the morning and regular crystalline insulin at bedtime (i.e., 16 to 18 hours after the morning insulin injection) can be tried. When different types of insulin are used in the same 24-hour period, the goal is to have the combined duration of effect of the insulins equal 24 hours. Differences in the potency of intermediate-and long-acting insulins versus regular crystalline insulin often necessitate the use of different dosages for the morning and evening insulin injections; regular crystalline insulin is more potent, and less is required to achieve the same glycemic effect, compared with Lente, NPH, PZI, and Ultralente insulins.

Figure 241-12 Categorization of types of commercial insulin based on potency and duration of effect. Note the inverse relationship between potency and duration of effect. (From Nelson RW, Couto CG: Small Animal Internal Medicine, 3rd ed. St Louis, Mosby, 2003, p 747.)



241.12.3.5 Inadequate or Impaired Insulin Absorption

Slow or inadequate absorption of subcutaneously deposited insulin is most commonly observed in diabetic cats receiving Ultralente insulin, a long-acting insulin that has a slow onset and prolonged duration of effect.[84,85] In approximately 25% of cats evaluated at our hospital, Ultralente insulin is absorbed from the subcutaneous site of deposition too slowly for it to be effective at maintaining acceptable glycemic control. In these cats, the blood glucose concentration may not decrease until 6 to 10 hours after the injection or, more commonly, it decreases minimally despite insulin doses of 8 to 12 U/cat given every 12 hours. As a consequence, the blood glucose concentration remains greater than 300 mg/dL for most of the day. We have had success in these cats by switching from Ultralente to Lente or PZI given twice a day.[85] When a change is made in the type of insulin, the insulin dosage is decreased (usually to amounts initially used to regulate the diabetic cat) to avoid hypoglycemia. The duration of effect of the insulin becomes shorter as the potency of the insulin increases, which may create problems with short duration of insulin effect (Figure 241-12). We have not yet identified similar problems with insulin glargine in diabetic cats, although our experience with this form of insulin is limited.

1588

1589

Impaired absorption of insulin may also occur as a result of thickening of the skin and inflammation of the subcutaneous tissues caused by chronic injection of insulin in the same area of the body. Rotation of the injection site helps prevent this problem.

241.12.3.6 Circulating Insulin Antibodies

Insulin antibodies result from repeated injection of a foreign protein (i.e., insulin). The structure and amino acid sequence of the injected insulin relative to the native endogenous insulin influences the development of insulin antibodies. Conformational insulin epitopes are believed to be more important in the development of insulin antibodies than differences in the linear subunits of the insulin molecule per se.[86] The more divergent the insulin molecule from the species, the greater the likelihood that significant or worrisome levels of insulin antibodies will develop. Canine and recombinant human insulin are similar, and the development of insulin antibodies is uncommon in dogs treated with recombinant human insulin.[87] In contrast, canine and beef insulin differ, and serum insulin antibodies have been identified in 40% to 65% of dogs treated with beef/pork or beef insulin.[10,86,87] In the author's experience, the presence of serum insulin antibodies is often associated with erratic and poor control of glycemia, frequent adjustments in the insulin dose to improve control, and the occasional development of severe insulin resistance. Dogs treated with recombinant human insulin have more stable control of glycemia for extended periods compared with dogs treated with beef insulin. Although uncommon, insulin antibodies can develop in dogs treated with recombinant human insulin and should be suspected as the cause of poor glycemic control when another cause cannot be identified. Documentation of serum insulin antibodies should use assays that have been validated in diabetic dogs. A switch to porcine source insulin or to a purer form of insulin (i.e., regular crystalline insulin), or both, should be considered if insulin antibodies are identified in a poorly controlled diabetic dog.

Fortunately, insulin antibody formation is not common in diabetic cats treated with exogenous human insulin despite the differences between human and feline insulin.[88] Two studies identified an approximately equal frequency of positive serum insulin antibody titers in diabetic cats treated with beef insulin compared with diabetic cats treated with recombinant human insulin.[14,89] In the author's experience, insulin antibody

titers are weakly positive in most cats, the prevalence of persistent titers is low, and serum insulin antibodies do not appear to affect control of glycemia. Overt insulin resistance caused by insulin antibody formation occurs in fewer than 5% of cats treated with recombinant human insulin. Switching from recombinant human insulin to beef/pork source PZI may improve control of glycemia if insulin antibodies are the suspected cause of insulin ineffectiveness.

241.12.3.7 Concurrent Disorders that Can Cause Insulin Resistance

Insulin resistance is a condition in which a normal amount of insulin produces a subnormal biologic response. Insulin resistance may result from problems occurring before the interaction of insulin with its receptor, at the receptor, or at steps distal to the interaction of insulin and its receptor. Prereceptor problems reduce free metabolically active insulin concentrations; such problems include an increase in insulin degradation or in insulin-binding antibodies. Receptor problems include alterations in the insulin-receptor binding affinity and concentration and the development of insulin-receptor antibodies. Postreceptor problems are difficult to differentiate clinically from receptor problems, and the two types often coexist. In dogs and cats, receptor and postreceptor abnormalities are usually attributable to obesity or to a disorder that causes excessive secretion of an insulin-antagonistic hormone (e.g., cortisol, glucagon, epinephrine, growth hormone, progesterone, or thyroid hormone).

No insulin dose clearly defines insulin resistance. For most diabetic dogs and cats, control of glycemia can usually be attained using 1 U or less of intermediate-or long-acting insulin per kilogram of body weight given twice daily. Insulin resistance should be suspected if control of glycemia is poor despite an insulin dosage in excess of 1.5 U/kg, when excessive amounts of insulin (i.e., greater than 1.5 U/kg) are necessary to maintain the blood glucose concentration below 300 mg/dL, and when control of glycemia is erratic and insulin requirements must be constantly changed in an attempt to maintain control of glycemia. Failure of the blood glucose concentration to decrease below 300 mg/dL during a serial blood glucose curve is suggestive of but not definitive for insulin resistance. An insulin resistance–type blood glucose curve can also result from stress-induced hyperglycemia, the Somogyi phenomenon, and other problems with insulin therapy (Box 241-6), and a decrease in the blood glucose concentration below 300 mg/dL can occur with disorders that cause relatively mild insulin resistance. Serum fructosamine concentrations are typically greater than 500 µmol/L in animals with insulin resistance and can exceed 700 µmol/L if resistance is severe.

In general, any concurrent inflammatory, infectious, hormonal, or neoplastic disorder can cause insulin resistance and can interfere with the effectiveness of insulin therapy (see Box 241-6). In the author's experience, the conditions or disorders that most commonly cause insulin resistance in dogs are treatment with diabetogenic drugs (glucocorticoids), severe obesity, hyperadrenocorticism, diestrus, chronic pancreatitis, renal insufficiency, oral and urinary tract infections, hyperlipidemia, and the development of insulin antibodies in dogs treated with beef insulin. The disorders that most commonly cause insulin resistance in cats are severe obesity, chronic pancreatitis, renal insufficiency, hyperthyroidism, oral infections, acromegaly, and hyperadrenocorticism. Obtaining a complete history and performing a thorough physical examination constitute the most important step in identifying these concurrent disorders. Abnormalities identified on the physical examination may suggest a concurrent insulin-antagonistic disorder or an infectious process, which gives the clinician direction in the diagnostic evaluation of the animal. If the history and physical examination findings are unremarkable, other diagnostic tests should be pursued to further screen for concurrent illness, including a complete blood count, serum biochemical analysis, serum thyroxine concentration (cat), serum progesterone concentration (intact female dog),

abdominal ultrasound scan, and urinalysis with bacterial culture. The use of additional tests depends on the results of the initial screening tests (Box 241-7).

241.12 CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Complications resulting from diabetes or its treatment are common in diabetic dogs and cats and include blindness and anterior uveitis resulting from cataract formation (dogs), peripheral neuropathy of the hind limbs, causing weakness, inability to jump, a plantigrade stance and ataxia (cats), chronic pancreatitis, recurring infections, hypoglycemia and ketoacidosis (see Box 241-5). Most of the devastating chronic complications of human diabetes (e.g., nephropathy, vasculopathy, and coronary artery disease) require 10 to 20 years or longer to develop and therefore are uncommon in diabetic dogs and cats. Diabetes mellitus is a disease of older dogs and cats, and most do not live beyond 5 years from the time of diagnosis.[12] In the author's experience, owners are usually willing to undertake the care of a diabetic pet once the fears related to chronic complications seen in human diabetics are alleviated.

1589

1590

241.13.1 Box • 241-6 Recognized Causes of Insulin Ineffectiveness or Insulin Resistance in Diabetic Dogs and Cats

241.13.1.1 Cause: Insulin Therapy

Inactive insulin

Diluted insulin

Improper administration technique

Inadequate dosage

Somogyi effect

Inadequate frequency of insulin administration

Impaired insulin absorption (especially with Ultralente insulin)

Anti-insulin antibody excess

241.13.1.2 Cause: Concurrent Disorder

Diabetogenic drugs

- glucocorticoids
- megestral acetate
- progestagens

Hyperadrenocorticism

Diestrus (bitch)

Acromegaly (cat)

Infection (especially of the oral cavity or urinary tract)

Hypothyroidism (dog)

Hyperthyroidism (cat)

Renal insufficiency

Liver insufficiency

Cardiac insufficiency

Glucagonoma (dog)

Pheochromocytoma

Chronic inflammation (especially pancreatitis)

Pancreatic exocrine insufficiency

Severe obesity

Hyperlipidemia

Neoplasia

241.13.2 Cataracts

Cataract formation is the most common chronic complication of diabetes mellitus in the dog. A retrospective cohort study on the development of cataracts in 132 diabetic dogs referred to a university hospital found cataract formation in 14% of dogs at the time diabetes was diagnosed and a time interval of 25%, 50%, 75%, and 80% of the study population to develop cataracts of 60, 170, 370, and 470 days, respectively.[90] The pathogenesis of diabetic cataract formation is thought to stem from altered osmotic relationships in the lens induced by the accumulation of sorbitol and fructose; these sugars are potent hydrophilic agents that cause an influx of water into the lens, leading to swelling and rupture of the lens fibers and the development of cataracts.[91] Cataract formation is an irreversible process once it begins, and it can occur quite rapidly. Diabetic dogs that are poorly controlled and that have problems with wide fluctuations in the blood glucose concentration seem especially at risk for rapid development of cataracts. Blindness may be eliminated by removal of the abnormal lens. Vision is restored in approximately 75% to 80% of diabetic dogs that undergo cataract removal. Factors that affect the success of surgery include the degree of glycemic control and whether retinal disease or lens-induced uveitis is present.

241.13.2.1

Box • 241-7 Diagnostic Tests to Consider in the Evaluation of Insulin Resistance in Diabetic Dogs and Cats

- Complete blood count (CBC), serum biochemistry panel, urinalysis
- Bacterial culture of the urine
- Serum lipase and amylase activities (pancreatitis)
- Serum trypsin-like immunoreactivity, pancreatic lipase immunoreactivity (exocrine pancreatic insufficiency, pancreatitis)
- Adrenocortical function tests
  - Adrenocorticotropic hormone (ACTH) stimulation test (spontaneous or iatrogenic hyperadrenocorticism)
  - Low-dose dexamethasone suppression test (spontaneous hyperadrenocorticism)
- Thyroid function tests
  - Baseline serum total and free thyroxine (hypothyroidism or hyperthyroidism)
  - Endogenous thyroid-stimulating hormone (TSH) (hypothyroidism)
  - TSH stimulation test (hypothyroidism)
  - Thyroid-releasing hormone stimulation test (hypothyroidism or hyperthyroidism)
  - Triiodothyronine suppression test (hyperthyroidism)
- Serum progesterone concentration (diestrus in intact female dog)
- Plasma growth hormone or serum insulin–like growth factor I concentration (acromegaly)
- Serum insulin concentration 24 hours after discontinuation of insulin therapy (insulin antibodies)

Serum triglyceride concentration (hyperlipidemia)

Abdominal ultrasonography (adrenomegaly, adrenal mass, pancreatitis, pancreatic mass)

Thoracic radiography (cardiomegaly, neoplasia)

Computed tomography or magnetic resonance imaging (pituitary mass)

241.13.3 Lens-Induced Uveitis

During embryogenesis, the lens is formed within its own capsule, and its structural proteins are not exposed to the immune system; consequently, immune tolerance to the crystalline proteins does not develop. During cataract formation and resorption, lens proteins are exposed to local ocular immune systems, resulting in inflammation and uveitis. Uveitis that occurs in association with a resorbing, hypermature cataract may decrease the success of cataract surgery and must be controlled before surgery. Treatment of lens-induced uveitis focuses on reduction of the inflammation and prevention of further intraocular damage. Topical ophthalmic corticosteroids are the drugs most commonly used to control ocular inflammation. However, systemic absorption of topically applied corticosteroids may cause insulin antagonism and thus interfere with glycemic control of the diabetic state, especially in toy and miniature breeds. An alternative is topical administration of nonsteroidal anti-inflammatory agents (e.g., 0.03% flurbiprofen) or cyclosporine.

1590

1591

241.13.4 Diabetic Neuropathy

Diabetic neuropathy is the most common chronic complication of diabetes in cats, with a prevalence of approximately 10% of cats with IDDM, but it is infrequently recognized in the diabetic dog. The cause of diabetic neuropathy is not known, although an alteration in polyol pathway activity may play a role in cats. The polyol pathway consists of two consecutive reactions: glucose first is reduced to sorbitol by aldose reductase and sorbitol subsequently is oxidized to fructose by sorbitol dehydrogenase. Aldose reductase is present in the Schwann cell, and accumulation of polyols (e.g., sorbitol, fructose) has been implicated in the pathogenesis of diabetic neuropathy. In a recent study, the severity of neurologic clinical signs and electrophysiologic abnormalities was best related to the blood glucose concentration; nerve water content was significantly elevated in diabetic versus healthy cats, nerve glucose and fructose were increased eightfold and twelvefold in diabetic versus healthy cats, respectively, and nerve myoinositol content in diabetic cats was reduced to 80% of the levels in healthy cats.[92] Myoinositol is a key element in many nerve cellular functions, and myoinositol depletion correlates with reduced nerve conduction velocity in diabetic nerves.[93,94] The role, if any, of other metabolic derangements, such as glycosylation of myelin, in the pathogenesis of diabetic neuropathy in cats remains to be determined.

Clinical signs of diabetic neuropathy include hindlimb weakness; impaired ability to jump; a plantigrade posture, with the cat's hocks touching the ground when it walks (see Figure 241-5); muscle atrophy, especially of the distal pelvic limb; depressed limb reflexes; deficits in postural reaction testing; and irritability on manipulation of the hindlimbs and feet.[92] Clinical signs may progress to include the thoracic limbs. Abnormalities on electrophysiologic testing, which are consistent with demyelination at all levels of the motor

and sensory peripheral nerves, include decreased motor and sensory nerve conduction velocities in the pelvic and thoracic limbs and decreased muscle action potential amplitudes.[92,95] Electromyographic abnormalities are usually absent but when identified are consistent with denervation. The most striking abnormality detected on histologic examination of nerve biopsies from affected cats is Schwann cell injury; axonal degeneration is identified in severely affected cats.

Currently, there is no specific therapy for diabetic neuropathy in cats. Aggressive glucoregulation with insulin may improve nerve conduction and reverse the posterior weakness and plantigrade posture in some diabetic cats (see Figure 241-5). However, the response to therapy is variable, and the risks of hypoglycemia increase with aggressive insulin treatment. Generally, the longer the neuropathy has been present and the more severe it is, the less likely improvement in glycemic control is to reverse the clinical signs.

241.13.5 Diabetic Nephropathy

Renal insufficiency and diabetes mellitus are common geriatric diseases that often occur concurrently, especially in older cats. Abnormal renal function may result from the deleterious effects of the diabetic state (i.e., diabetic nephropathy), or it may be an independent problem that develops in conjunction with diabetes in the geriatric pet. Histopathologic findings in diabetic nephropathy depend on the duration of the disease prior to evaluation of the dog or cat and on the degree of glycemic control; these findings include membranous glomerulonephropathy with fusion of the foot processes, glomerular and tubular basement membrane thickening, an increase in the mesangial matrix material, the presence of subendothelial deposits, glomerular fibrosis, and glomerulosclerosis. The pathogenic mechanism of diabetic nephropathy is unknown but is undoubtedly multifactorial. Clinical signs depend on the severity of glomerulosclerosis and the functional ability of the kidney to excrete metabolic wastes. Initially, diabetic nephropathy is manifested as severe proteinuria, primarily albuminuria, as a result of the glomerular dysfunction. As the glomerular changes progress, glomerular filtration becomes progressively impaired, resulting in the development of azotemia and eventually uremia. With severe fibrosis of the glomeruli, oliguric and then anuric renal failure develops. No specific treatment is available for diabetic nephropathy, apart from meticulous metabolic control of the diabetic state, conservative medical management of the renal insufficiency, and control of systemic hypertension.

241.14 PROGNOSIS

The prognosis for dogs and cats diagnosed with diabetes mellitus depends in part on the owners' commitment to treating the disorder, the ease of glycemic regulation, the presence and reversibility of concurrent disorders, and the avoidance of chronic complications associated with the diabetic state. The mean survival time for diabetic dogs and cats is approximately 3 years from the time of diagnosis, although survival time is somewhat skewed because dogs and cats are usually 7 years or older at the time of diagnosis, and the mortality rate during the first 6 months is relatively high because of concurrent life-threatening or uncontrollable disease (e.g., ketoacidosis, acute pancreatitis, renal failure).[12] Diabetic dogs and cats that survive the first 6 months can easily maintain a good quality of life for longer than 5 years with proper care by the owners, timely evaluations by the veterinarian, and good client-veterinarian communication.

242 CHAPTER • 242 Hyperadrenocorticism

Claudia E. Reusch

242.1 HYPERADRENOCORTICISM IN DOGS

In 1932 Dr. Harvey Cushing, a neurosurgeon, documented the presence of small, basophilic pituitary adenomas in human patients with clinical signs of adrenocortical hyperfunction. Years later, it was found that these tumors produced excess adrenocorticotropic hormone (ACTH), with resultant bilateral adrenocortical hyperplasia. In humans as well as in dogs and cats, pituitary ACTH hypersecretion (Cushing's disease) is now recognized as the most common cause of naturally occurring hyperadrenocorticism (Cushing's syndrome). This condition must be distinguished from other natural causes, such as non-ACTH-dependent adrenocortical tumors and ACTH-secreting nonpituitary tumors (ectopic ACTH syndrome). The latter disorder has not been described in dogs and cats. It is also necessary to differentiate naturally occurring hyperadrenocorticism from iatrogenic causes, which result from chronic glucocorticoid therapy and probably constitute the majority of cases of hyperadrenocorticism.

242.2 HYPOTHALAMUS–ADENOHYPOPHYSIS–ADRENAL GLAND AXIS

Neurotransmitters from the central nervous system (CNS) modulate the release of hypophysiotropic hormones, such as corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP), from neurons in the hypothalamus. Both CRH and AVP are considered the predominant stimulating neurohormones for ACTH secretion *in vivo*.[1] CRH consists of 41 aminoacids, and its structure is identical in humans, dogs, rats, and horses.[2] CRH and AVP are released into the hypothalamohypophyseal portal blood system and travel to the corticotropic cells in the anterior pituitary, where they stimulate the release of ACTH. ACTH is a single-chain polypeptide comprising 39 amino acids. The amino acid sequence of ACTH is highly conserved. In all mammals studied thus far, the first 24 amino acids are identical. Canine ACTH differs from human ACTH by only one amino acid residue, at position 37. It is synthesized from a well-characterized precursor molecule, pro-opiomelanocortin (POMC), which also gives rise to a variety of other peptides coreleased with ACTH.

In contrast to humans, the adenohypophysis of dogs and cats has a pars distalis and a discrete pars intermedia (Figure 242-1). The processing of POMC and the regulation of ACTH secretion differ between these two parts. The pars distalis produces mainly ACTH and beta lipotropin (beta-LPH). The pars intermedia contains two cell types and processes alpha melanocyte-stimulating hormone (alpha-MSH) and corticotropin-like intermediate lobe peptide (CLIP) in the predominant A cells. The B cells of the pars intermedia resemble the corticotrophs of the pars distalis, and cleavage of POMC is mainly into ACTH and beta-LPH (Figure 242-2). In the pars intermedia, the release of POMC-derived peptides is largely regulated by tonic dopaminergic inhibition.[3] It has long been assumed that the pars intermedia does not actively secrete ACTH into the circulation. However, the results of a recent study in dogs suggest that the pars intermedia may contribute to circulating ACTH concentrations.[4] The physiologic function of peptides processed from POMC is an exciting area of neuroendocrine research that requires further investigation.

In the adrenal cortex, ACTH stimulates the synthesis and secretion of several hormones, specifically glucocorticoids and androgenic steroids in the zona fasciculata and zona reticularis and mineralocorticoids in the zona glomerulosa. The effect of ACTH is rapid; within minutes, plasma levels of these hormones rise. Because aldosterone is mainly regulated by the renin-angiotensin system and plasma potassium concentrations and

because the amount of androgens produced is small, ACTH exerts its most important effect on glucocorticoids. The synthesis and release of glucocorticoids are almost exclusively controlled by ACTH. Cortisol is the major glucocorticoid, and this is the term used to describe glucocorticoids in the following section. Cortisol in turn inhibits ACTH release.

In summary, cortisol secretion is closely regulated by ACTH, and plasma levels of cortisol parallel those of ACTH.

Four mechanisms effect neuroendocrine control:

- Secretion of ACTH in an ultradian pulsatile fashion, which is influenced by the hypothalamus. The number of pulses ranges from six to 12 per 24-hour period.
- Stress responsiveness of the hypothalamus–adenohypophysis–adrenal gland axis. ACTH and cortisol are secreted within minutes after the onset of stress. Stress originates in the CNS and causes increased release of CRH and AVP.
- Feedback inhibition of ACTH by cortisol. Cortisol acts at multiple target sites, two of which have been identified: neurons in the hypothalamus that produce CRH and AVP, and corticotropic cells in the anterior pituitary. Two kinds of feedback are discussed: *fast feedback,* which occurs rapidly and inhibition of which affects stimulated but not basal secretion, and *slow feedback,* which depends on steroid levels and leads to a decrease in ACTH synthesis. Inhibition of slow feedback affects both basal and stimulated ACTH release.
- Release of interleukin-1, interleukin-6, tissue necrosis factor, and other cytokines associated with infection, which activates the hypothalamus–pituitary–adrenal gland axis.

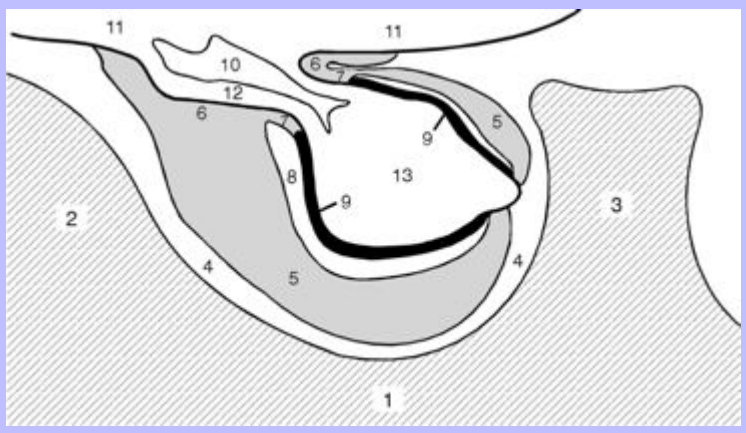
242.3 ETIOPATHOLOGY

242.3.1 Cushing's Disease (Pituitary-Dependent Hyperadrenocorticism)

Approximately 80% to 85% of dogs with naturally occurring hyperadrenocorticism suffer from pituitary-dependent hyperadrenocorticism (PDH), which is characterized by overproduction of ACTH (Figure 242-3). In many cases the pituitary lesions are small adenomas, although in some dogs large tumors, usually adenomas, are found. Pituitary carcinomas, which appear to be rare in dogs, may invade surrounding structures.[5] In a small percentage of dogs with ACTH-dependent disease, corticotropic cell hyperplasia occurs rather than a tumor. Whether hyperplastic lesions occur exclusively or small pituitary tumors are missed during histopathologic examination is a matter of debate.

1592 1593

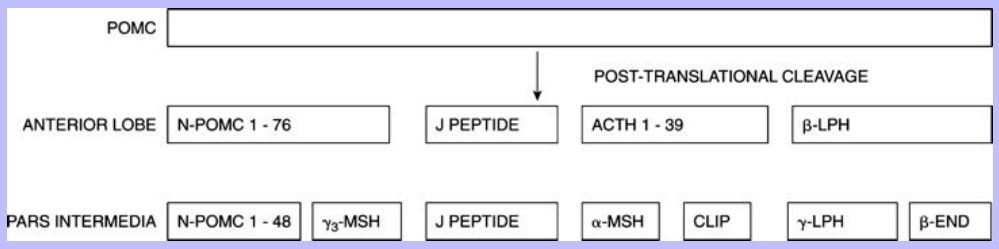
Figure 242-1 Schematic illustration of a median sagittal section through the canine pituitary gland. (Left is rostral, right is caudal.) *1,* Sphenoid bone; *2,* tuberculum sellae; *3,* dorsum sellae; *4,* pituitary fossa; *5,* pars distalis adenohypophysis; *6,* pars infundibularis adenohypophysis; *7,* transitional zone; *8,* hypophyseal cleft or cavity; *9,* pars intermedia adenohypophysis; *10,* third ventricle; *11,* hypothalamus (median eminence); *12,* pars proximalis neurohypophysis; *13,* pars distalis neurohypophysis. (From Meij B: Hypophysectomy as a treatment for canine and feline Cushing's disease. Vet Clin North Am Small Anim Pract 31:1021, 2001.)



In about 70% of dogs with PDH the tumors originate in the pars distalis, whereas in about 30% they arise either from the A cells or the B cells of the pars intermedia.[6]

Two hypotheses have been proposed for the pathogenesis of PDH. According to one hypothesis, the disease results from a defect at the hypothalamic level. Secretion of ACTH from the pars intermedia is controlled by tonic dopaminergic inhibition, and some evidence indicates that dopamine affects the pars distalis of the adenohypophysis. A decrease in the central dopamine concentration has been proposed to result in dysregulation of the hypothalamic–adenohypophysis–adrenal gland axis and, in turn, overproduction of ACTH and possible tumor formation.[7] According to the other hypothesis, PDH is caused by a primary pituitary defect, and increasing evidence substantiates this, such as the monoclonal character of corticotropic adenomas,[8] the occurrence of secondary adrenal insufficiency after selective resection of tumors,[9] and the low CRH concentration in the cerebrospinal fluid of dogs with PDH.[10] The current view is that corticotropic adenomas are the result of a complex, multistage process of tumorigenesis. The earliest stage may be an inherited aberration that plays an initiating or promoting role. A report of the occurrence of PDH in a family of seven Dandie Dinmont terriers supports the role of genetic factors.[11] Clonal expansion of the genomically altered cell may be caused by an intrinsic mutation that results in activation of cell replication; by extrinsic factors, such as intrapituitary growth factors; or by both these mechanisms.[12]

Figure 242-2 Processing of pro-opiomelanocortin (POMC) in the anterior lobe and in the pars intermedia of the pituitary gland. *J Peptide,* Joining peptide; *LPH,* lipoprotein; *MSH,* melanocyte-stimulating hormone; *CLIP,* corticotropin-like intermediate lobe peptide; *END,* endorphin.



Some reports have addressed pituitary tumor size in dogs. The most extensive tumor proliferation was encountered in dogs with a strong resistance to dexamethasone, therefore it was postulated that a pituitary tumor's growth potential depends on the degree of insensitivity to glucocorticoid feedback.[13] Whether large tumors are more likely to arise from the pars intermedia than the pars distalis has long been the subject of debate. Because the pars intermedia lacks glucocorticoid receptors and extensive tumors appear to be resistant to glucocorticoids, tumors originating in the pars intermedia may grow larger than those in the pars distalis. However, it has also been stated that pituitary tumors do not always maintain the characteristics of the cells of origin and that PDH cannot be simply divided into either pars distalis or pars intermedia type by plasma alpha-MSH levels or dexamethasone resistance.[14]

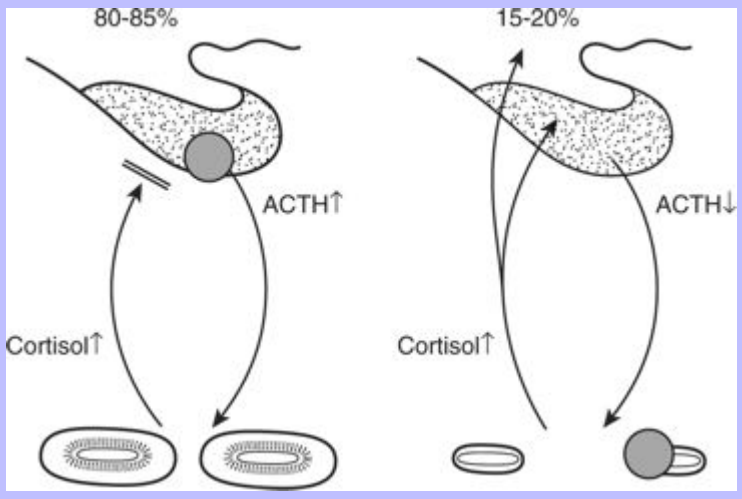
Another characteristic of corticotropic adenomas is their ability not only to produce ACTH but also to release excessive amounts of ACTH precursors. In dogs with PDH, the ACTH precursor concentration is significantly higher in animals with large pituitary tumors compared with those with small tumors.[15] It is important to be aware of this phenomenon as a clinician. ACTH precursors have low biologic activity, therefore dogs with (large) pituitary tumors may have only subtle or no clinical signs of hyperadrenocorticism.

PDH is also associated with alterations in the release of several pituitary hormones. It generally is agreed that glucocorticoids inhibit the release of AVP in dogs. A recent study found that, compared with controls, dogs with PDH had higher basal plasma levels of prolactin, lower levels of growth hormone (GH), and similar levels of luteinizing hormone (LH) and thyroid-stimulating hormone (TSH).[16]

242.3.1.1 Functional Adrenocortical Tumor

Among dogs and cats with naturally occurring hyperadrenocorticism, 15% to 20% have a functional adrenocortical tumor (FAT), which secretes cortisol independent of pituitary control. Cortisol in turn suppresses CRH in the hypothalamus and ACTH in the pituitary gland. The result of this chronic negative feedback is cortical atrophy of the uninvolved adrenal gland and atrophy of all normal cells in the involved adrenal gland (see Figure 242-3). 1593 1594

Figure 242-3 Simplified schematic of the pituitary-adrenal axis in dogs with pituitary-dependent hyperadrenocorticism *(left)* and with functional adrenal tumor *(right)*.



For many years it was assumed that adrenocortical tumors produced large amounts of hormone, more in fact than hyperplastic adrenal glands of dogs with PDH. However, the opposite appears to be true; in many dogs with an FAT, the hormone excess and subsequent clinical signs are only moderate. Therefore, even though adrenocortical tumors usually greatly exceed the size of the normal adrenal gland, the tumor tissue is only moderately active, and the neoplastic transformation results in a decreased degree of function per unit of volume.[17] It is also possible that the cortisol synthesis pathway in dogs with an FAT is not intact. In humans, adrenal carcinomas tend to produce large amounts of intermediates in the biosynthesis of cortisol, and a partial or complete deficiency of 11-beta-hydroxylase is common. The existence of a similar phenomenon in dogs has recently been suggested.[18]

In dogs with an FAT, the right and left adrenal glands are affected with equal frequency. Usually a unilateral, solitary adrenal mass is seen, although bilateral tumors are found in approximately 10% of cases.

Information in the literature on the incidence of adenomas and carcinomas varies, but the two tumor types probably occur with equal frequency. As with other endocrine tumors, it is difficult to distinguish between adrenal adenomas and adrenal carcinomas. Differentiation of adrenocortical tumors and pheochromocytoma may require a pathologist with experience in special immunohistochemical staining techniques. In some cases adrenocortical tumors that initially had been diagnosed as benign turned out to be malignant when metastases were discovered later.

Histologic differentiation between benign and malignant tumors is straightforward only when capsular or vascular invasion by the tumor has occurred. Otherwise, it is difficult to establish the biologic nature of the tumor, and distant metastasis may not occur.[19] Interestingly, it is not uncommon for adrenocortical tumors to be associated with pheochromocytoma.[17]

242.3.1.2 Simultaneous Occurrence of Pituitary and Adrenocortical Tumors

The co-existence of pituitary and adrenal tumors was recently described in 17 dogs with hyperadrenocorticism. Necropsy or surgery demonstrated unilateral adrenocortical adenoma with contralateral adrenal hyperplasia in 10 dogs; bilateral adrenal cortical adenoma in four dogs; and adrenal carcinoma with contralateral hyperplasia in three dogs. Pituitary lesions included a chromophobe microadenoma in 12 dogs; pituitary macroadenoma in four dogs; and pituitary carcinoma in one dog.[20] Two years later the study was revised, and it was speculated that some of these dogs actually may have had a condition similar to macronodular adrenal hyperplasia in humans.[21]

242.3.1.3 Adrenocortical Nodular Hyperplasia

In humans, bilateral nodular hyperplasia with hyperadrenocorticism has been identified as a sequel to several pathophysiologic conditions. Long-standing ACTH hypersecretion may result in nodular enlargement of the adrenal gland. Over time, these nodules may become autonomous or semiautonomous. Another type of nodular hyperplasia has been called *massive macronodular adrenal hyperplasia*. This type is ACTH independent and is characterized by bilateral large nodules that secrete excessive amounts of cortisol. This condition suggests that non-ACTH factors may induce cortisol secretion.[22] Recent studies indicate that receptors for various hormones may be abnormally expressed by the adrenal glands; for example, ectopic expression of the gastric inhibitory polypeptide receptor has been convincingly demonstrated.[23] This polypeptide stimulates the release of cortisol *in vivo* and *in vitro*. It is assumed that adrenocortical nodular hyperplasia also exists in dogs, although studies currently are lacking.

242.3.1.4 Clinical Findings

Hyperadrenocorticism, or Cushing's syndrome, is one of the most common endocrinopathies in dogs. The clinical signs and laboratory results in dogs with hyperadrenocorticism are largely attributable to chronic glucocorticoid excess and, to a much lesser extent, overproduction of adrenal androgens. In a few cases, symptoms are due to tumor growth, local invasion of tumors, or metastases.

242.3.1.5 Signalment

Dogs with naturally occurring hyperadrenocorticism are usually 6 years of age or older (the average age is 9 to 11 years). Of 100 dogs with Cushing's syndrome diagnosed in our clinic, only five were younger than 6 years, and all had PDH: two of the dogs were 5 years old (a German shepherd and a dachshund), one was 4 years old (a cocker spaniel), and two were 2 years old (a weimaraner and a puli). Dogs with an FAT tend to be older than dogs with PDH.[24]

A number of different breeds and mixed breeds with hyperadrenocorticism have been reported. The most commonly represented breeds are poodles, dachshunds, beagles, boxers, and various terrier breeds. Approximately 75% of dogs with PDH weigh less than 20 kg.[24] FAT most often occurs in poodles, German shepherds, dachshunds, Labrador retrievers, and various terrier breeds. Approximately 45% to 50% of dogs with an FAT weigh more than 20 kg.[24] Between 55% and 60% of dogs with hyperadrenocorticism are female.[24]

242.3.1.6 History and Physical Examination

Dogs with hyperadrenocorticism may have a number of dramatic clinical signs, although affected animals are usually in stable condition. Severe apathy, vomiting, diarrhea, muscle pain, and anorexia are not characteristic symptoms of Cushing's syndrome, therefore these signs indicate another disease or complications of hyperadrenocorticism (see below).

The clinical signs of hyperadrenocorticism are the sequelae to the combined gluconeogenic, immune-suppressive, anti-inflammatory, protein catabolic, and lipolytic effects of glucocorticoids exerted on various organ systems. PDH cannot be distinguished from FAT on the basis of the type or duration of symptoms. 1594 1595

Clinical signs, which may vary from mild to severe, depend on the duration of the disease and the degree of cortisol excess. Usually the course of hyperadrenocorticism is insidious and slowly progressive. Rarely, clinical signs are intermittent, with periods of remission and relapse in dogs with mild disease.[25] Fewer dogs are presented with severe clinical signs today than in years past, probably because of today's owners' heightened awareness of their pets' problems. Consequently, diagnosis of the disease may be more difficult in dogs with mild symptoms.

Typical symptoms include polydipsia, polyuria, polyphagia, truncal obesity or abdominal enlargement (due to hepatomegaly, muscle wasting and/or intra-abdominal fat accumulation), thin haircoat, failure to regrow shaved hair, alopecia (may or may not be bilaterally symmetric, usually sparing the head and extremities), thin skin, pyoderma, panting, muscle weakness, muscle atrophy and lethargy. Less common signs are heat intolerance, seborrhea, comedones, hyperpigmentation, calcinosis cutis, bruising, testicular atrophy, failure to cycle, clitoral hypertrophy, and facial paralysis (Table 242-1). In rare cases (five out of 800 dogs),[26] affected dogs develop a characteristic stiff gait, most often restricted to the pelvic limbs, called *myotonia* or *myotonia-like syndrome*.

It is important to note that the number and severity of these signs vary remarkably. Dogs with Cushing's syndrome may have only one sign or may have almost all the signs listed. In our clinic, 30% of the dogs with hyperadrenocorticism had only polydipsia and polyuria, and 10% had only dermatologic problems (Figure 242-4).

Dogs that develop Cushing's syndrome during the first year of life show weight gain and growth retardation in addition to more typical signs (i.e., polydipsia, polyuria, and alopecia).[26]

242.3.1.7 Clinicopathologic Findings

When the results of the clinical examination lead to a presumptive diagnosis of Cushing's syndrome, further diagnostic testing is required, including hematology, a biochemical profile, urinalysis, radiography and, when applicable, ultrasonography. These tests detect typical abnormalities associated with hyperadrenocorticism and rule out other diseases with similar signs, such as chronic renal failure, diabetes mellitus, liver diseases, hypothyroidism, diabetes insipidus, and the side effects of anticonvulsant drugs. Concomitant problems, such as urinary tract infection, can also be investigated. A definitive diagnosis of Cushing's syndrome necessitates specific tests.

242.3.1.7.1

Hemogram

Under the influence of increased glucocorticoids, most dogs develop a so-called stress leukogram, which is characterized by neutrophilia without a left shift, lymphopenia, eosinopenia, and monocytosis. Neutrophilia does not imply greater resistance to infection in affected dogs, because cell function is impaired. Not all changes are present in dogs with hyperadrenocorticism, but lymphopenia and eosinopenia are the most consistent abnormalities. It should be emphasized that a stress leukogram is a nonspecific finding that occurs in many sick dogs. In our clinic, 87% of the dogs with hyperadrenocorticism have thrombocytosis, with counts ranging from 403,000 to 1,140,000 platelets/μL.

242.3.1.7.2

Biochemical profile

About 85% to 95% of dogs with hyperadrenocorticism show increases in serum alkaline phosphatase (ALP) activity. This is partly due to the induction of a glucocorticoid isoenzyme, which is unique to the dog and is a hyperglycosylated form of the intestinal isoenzyme.[27] Some maintain that determination of the levels of this isoenzyme is a valuable test in the diagnosis of hyperadrenocorticism. Several methods, such as levamisole inhibition[28] and heat inactivation,[29] have been described. Although these tests have a high sensitivity, their lack of specificity makes them unsuitable as diagnostic tests. The increase in ALP activity may be dramatic; levels above 1000 U/L are frequently seen. However, no correlation exists between ALP activity and the severity of hyperadrenocorticism, the response to therapy, or the prognosis.[26]

Table • 242-1 Clinical Signs in Dogs with Hyperadrenocorticism

CLINICAL SIGN	INCIDENCE (% OF CASES)
Polydipsia/polyuria	80–91
Alopecia	60–74
Pendulous abdomen	67–73
Hepatomegaly	51–67
Polyphagia	46–57
Muscle weakness	14–57
Anestrus	54
Muscle atrophy	35
Comedones	25–34
Panting	30
Hyperpigmentation	23–30
Testicular atrophy	29
Calcinosis cutis	8–15
Facial nerve paralysis	7

Modified from Ling et al 1979; Peterson ME: Hyperadrenocorticism. *In* Peterson ME (ed): The Veterinary Clinics of North America, Small Animal Pracitce—Endocrinology. Philadelphia, WB Saunders, 1984, p 731; and unpublished data from the author. Not all symptoms were mentioned in all three studies, therefore the number of dogs varies among the symptoms. The total number of dogs in the three studies was 457.

*From the history and physical examination.

In 50% to 80% of dogs, a mild increase in alanine aminotransferase (ALT) activity is seen (less than 400 IU/L), which is attributed to hepatocellular leakage associated with cell swelling or minor necrosis. Mild to moderate increases in the cholesterol and triglyceride concentrations are common (50% to 90% of dogs) and are believed to be the result of increased lipolysis. Often affected dogs have alterations in

glucose metabolism, although only about 10% of dogs develop overt diabetes mellitus. Mild fasting hyperglycemia may be seen in 30% to 40% of dogs. The blood urea nitrogen and creatinine concentrations are low as a result of diuresis in about 30% to 50% of cases. Hypophosphatemia has been described in 38% of 300 dogs with hyperadrenocorticism.[30] Mild increases in the sodium concentration and mild decreases in the potassium concentration occur in few dogs with Cushing's syndrome.

Serum bile acids may be mildly elevated in up to 30% of cases.[31] When primary liver disease is considered a major differential diagnosis, this finding, together with an elevation in liver enzymes, may be confusing (Table 242-2).

242.3.1.7.3

Urinalysis

Urinalysis is an important part of the diagnostic workup. It is recommended that owners obtain a urine sample for determination of the specific gravity at home. Collection of a urine sample in hospitalized dogs with Cushing's syndrome is not recommended, because water intake often is decreased in a stressful environment. Most water-deprived dogs with hyperadrenocorticism are able to concentrate the urine, with specific gravities reaching 1.025 to 1.035. In 85% of dogs with Cushing's syndrome, the urine specific gravity of samples obtained at home is less than 1.015 to 1.020.[26] Glucosuria occurs in dogs with overt diabetes mellitus. Glucose is not found in the urine of dogs with hyperglycemia below the renal threshold. Many dogs with hyperadrenocorticism have proteinuria, which in some may be due to urinary tract infection. The urine protein/creatinine ratio in dogs with Cushing's syndrome usually ranges from 1.0 to 6.0 (normal is less than 1.0).

Philadelphia, WB Saunders, 1984, p 731; Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 2nd ed. Philadelphia, WB Saunders, 1996, p 187; and from unpublished data from this author.

ALP, Alkaline phosphatase; *ALT,* alanine aminotransferase; *BUN,* blood urea nitrogen; *UPC,* urine protein concentration.

* Only about 10% of dogs develop overt diabetes mellitus.

Long-term administration of glucocorticoids results in glomerular lesions and proteinuria in dogs.[32] The mechanisms by which glucocorticoids cause glomerular disease are not yet fully understood. Glucocorticoids may enhance the development of antigen excess by delaying clearance of immune complexes. Glomerular damage may also be caused by hypertension; many dogs with hyperadrenocorticism are hypertensive, and a relationship between hypertension and proteinuria has been postulated.[33] Proteinuria in dogs with hyperadrenocorticism does not lead to hypoalbuminemia.

Almost 50% of dogs with hyperadrenocorticism have a urinary tract infection,[34] and bacterial culture of a urine sample obtained by cystocentesis should be performed in all such dogs. As a result of immunosuppression and/or dilution, urinary sediment frequently is inactive despite bacterial infection, therefore sediment examination must not replace urine culture.

242.3.1.7.4

Thyroid function tests

More than 50% of dogs with hyperadrenocorticism have a total serum thyroxine (T_4) concentration below the reference range. Free T_4 is low in about 25% of cases.[35] Possible mechanisms include alterations in serum thyroid hormone binding and/or alterations in peripheral hormone metabolism. Glucocorticoids may also suppress TSH release from the pituitary. In dogs with clinical signs suggestive of both hyperadrenocorticism and hypothyroidism (alopecia, weight gain, lethargy), diagnosis may be difficult, and misdiagnosis may occur if the endocrine tests are not carried out in the correct order. In such cases, hyperadrenocorticism must be ruled out before tests for hypothyroidism are performed. Determination of the circulating thyroid-stimulating hormone (cTSH) concentration is not always helpful; although dogs with Cushing's syndrome usually have normal or decreased cTSH concentrations, about one third of dogs with hypothyroidism have low-normal cTSH concentrations.[36–38] Thyroid

hormone supplementation is thought to be unnecessary because thyroid hormone concentrations return to normal after successful treatment of hyperadrenocorticism.

242.3.1.7.5 Diagnostic imaging

242.3.1.7.5.1 Thoracic radiographs

Radiographic manifestations of hyperadrenocorticism include mineralization of the tracheobronchial tree and pulmonary parenchyma. Although these abnormalities appear to be significantly more common in dogs with hyperadrenocorticism, they are considered nonspecific.[39] Even though the clinical consequences have not been fully elucidated, pulmonary mineralization may contribute to the hypoxemia seen in dogs with hyperadrenocorticism.[40]

In dogs with an adrenal tumor, thoracic radiographs should be examined for metastases. Pulmonary thromboembolism is a potential complication of hyperadrenocorticism (see below). In dogs with sudden onset of dyspnea, radiographs should be carefully evaluated for abnormalities.

242.3.1.7.5.2 Abdominal radiographs

Radiographic findings associated with Cushing's syndrome are hepatomegaly, obesity, and good contrast and mineralization of the adrenal glands and other soft tissue structures. However, it was recently shown that hepatomegaly, obesity, and osteopenia are nonspecific and also may be seen in dogs with diabetes mellitus or hypothyroidism. The same study also reported that adrenal mineralization and calcinosis cutis were rarely seen and only in dogs with hyperadrenocorticism.[39] Approximately 50% of adrenal tumors are calcified, which allows good radiographic visualization. No difference is seen between adenomas and carcinomas regarding calcification; approximately 50% of both types undergo calcification.[41]

242.3.1.7.5.3 Ultrasonograph

An increase in experience among radiologists and improved resolution of imaging equipment have made visualization of the adrenal glands possible in almost all healthy dogs. However, a systematic approach is necessary for accurate identification and evaluation of the glands. Measurement of the dorsoventral dimension (thickness) appears to be the most accurate means of assessing size. Normal thickness has been reported to be 3 to 7.5 mm.[42,43] In dogs with PDH, the adrenal glands have a bilaterally symmetric appearance. It is important to remember that the absolute adrenal thickness is of limited diagnostic value because reference ranges have been established with limited numbers of dogs; different breeds may have different reference ranges; diseases other than hyperadrenocorticism may cause adrenomegaly (possibly stress related); and the measurement may be within the reference range of a dog population but may be enlarged for an individual dog. Ultrasonography, therefore, should not be used to diagnose Cushing's syndrome but rather to differentiate PDH from FAT. The shape and echogenicity of the adrenal glands in dogs with PDH are usually normal although focal areas of increased echogenicity and loss of the bilayer appearance are possible.

In comparison, the affected adrenal gland of a dog with an FAT often has an irregular, rounded shape with mixed echogenicity. In some cases the tumor appears as a homogenous nodule (Figure 242-5).

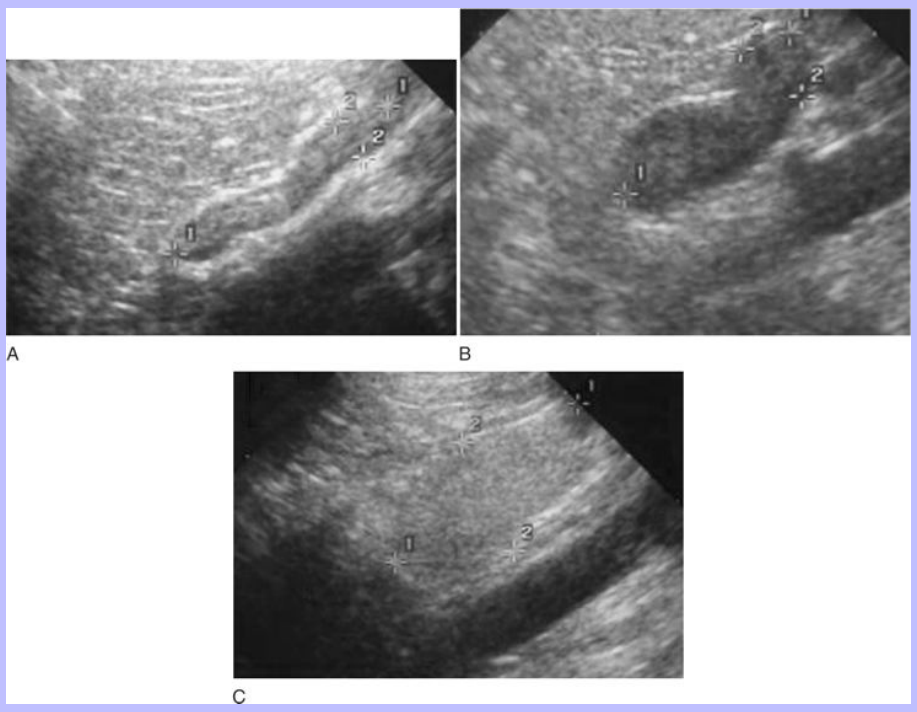
The size and shape of adrenal tumors are variable and do not allow differentiation between adenoma and carcinoma. In a study of a small number of dogs with an FAT, all tumors of a thickness greater than 4 cm were malignant.[44] Therefore the likelihood that an adrenal tumor is malignant may increase as its size increases. Other possible ultrasonographic findings include adrenal mineralization, renal displacement, and compression or invasion of the caudal vena cava (Doppler ultrasonography is a valuable tool for diagnosing compression or invasion). Both adrenal glands should always be visualized, for several reasons: (1) bilateral tumors do occur; (2) in quite a few dogs, the adrenal gland contralateral to an adrenal tumor is not decreased in size, and the diagnosis would be missed if only the normal gland is imaged[45]; and (3) concurrent FAT and PDH are possible.

1597

1598

Ultrasonography is useful for detecting local invasion and distant metastases in dogs with an FAT and for revealing other abnormalities, such as urinary calculi and an enlarged renal pelvis (indicating pyelonephritis). In most dogs with hyperadrenocorticism, the liver is enlarged and has increased echogenicity. As with most diagnostic tools, ultrasonography has its limitations; it is difficult or impossible to differentiate between bilateral nodular hyperplasia and bilateral adrenal tumors, and between an FAT and other adrenal tumors (e.g., pheochromocytoma or metastatic tumor).

Figure 242-5 **A,** Longitudinal ultrasonographic view of the left adrenal gland of a healthy dog. The adrenal gland is peanut shaped and hypoechoic compared to the surrounding tissue. It is 2.9 cm long and 0.5 cm wide (thick). **B,** Longitudinal ultrasonographic view of the left adrenal gland of a dog with pituitary-dependent hyperadrenocorticism. The adrenal gland is still peanut shaped, but it is plumper than the one shown in **A.** This adrenal gland is 2.4 cm long and 0.8 cm wide (thick). It should be noted that measurements have limited diagnostic value, because the adrenal size of a variety of dogs with pituitary-dependent hyperadrenocorticism falls within reference ranges. **C,** Longitudinal ultrasonographic view of a right-sided adrenocortical tumor. The adrenal gland is seen as a rounded mass with increased echogenicity (length, 2.7 cm; width [thickness], 1.3 cm).



242.3.1.7.6 Specific endocrine testing

Further diagnostic workup of dogs suspected of having Cushing's disease is a two-step procedure. The first step is to confirm hyperadrenocorticism, and the second is to differentiate between PDH and FAT. Because the treatment protocols and risks are different for PDH and FAT, the second step should always be undertaken. In dogs with a unilateral adrenal tumor, adrenalectomy may be the treatment of choice, although owners should be informed of the risk of metastasis (approximately 50% of FATs are carcinomas). When mitotane is the chosen treatment, the dose usually is higher for dogs with FAT than for those with PDH. Therefore, if the etiology is unknown, dogs that have an FAT may not respond to a dose of mitotane tailored for treatment of PDH. In addition, it is important to diagnose an FAT correctly so that owners can be informed of the risk of tumor growth.

The screening tests used routinely in the diagnosis of hyperadrenocorticism are the urine cortisol to creatinine (C:C) ratio, the ACTH stimulation test, and the low-dose dexamethasone test. The question as to which of these is the best screening test is difficult to answer; each has advantages and disadvantages. For a sound interpretation of these tests, their accuracy, sensitivity, and specificity must be considered, as well as the prevalence of the disease. As a general rule, it is extremely important that dogs be carefully selected for testing and that the test be delayed if concomitant disease is a factor. Also, test results should be interpreted in relation to clinical signs.

1598

1599

Differentiating tests for hyperadrenocorticism include the extended low-dose dexamethasone test, high-dose dexamethasone test, extended urine C:C ratio, measurement of the ACTH concentration, adrenal ultrasonography, computed tomography (CT) and magnetic resonance imaging (MRI).

242.3.1.7.7 Screening tests

242.3.1.7.7.1 Urine cortisol to creatinine ratio

Measurement of the urine C:C ratio is an easily performed test of adrenocortical function. In animals with hyperadrenocorticism, urine cortisol excretion increases as a reflection of augmented adrenal cortisol secretion.[46] Determination of the urine C:C ratio provides an integrated picture of glucocorticoid production by adjusting for fluctuations in plasma levels.[47] Numerous studies on the diagnostic value of the urine C:C ratio[48] have concluded that this test has a high sensitivity (up to 100%) but a low specificity (values as low as 20% are given) (Figure 242-6). Therefore determination of the urine C:C ratio has been advocated as a good test for ruling out hyperadrenocorticism.

Several important points should be considered when the urine C:C ratio is used. Most corticoid measured in the urine is free cortisol. However, depending on the assay used, varying amounts of cortisol metabolites may be detected. It is imperative, therefore, that each laboratory generate its own reference ranges. It is preferable that morning urine samples be submitted, although no consistent diurnal fluctuations have been demonstrated.[46] Also, urine samples for determination of the cortisol/creatinine ratio should be collected at home by the owner to avoid the influence of stress on glucocorticoid secretion.[49]

When the urine C:C ratios of 111 dogs with PDH were compared with those of 49 dogs with an FAT, the highest values were found in dogs with PDH. In dogs with a urine C:C ratio greater than 100×10^{-6} (reference range, less than 10×10^{-6}), the calculated probability of PDH is 90%.[50]

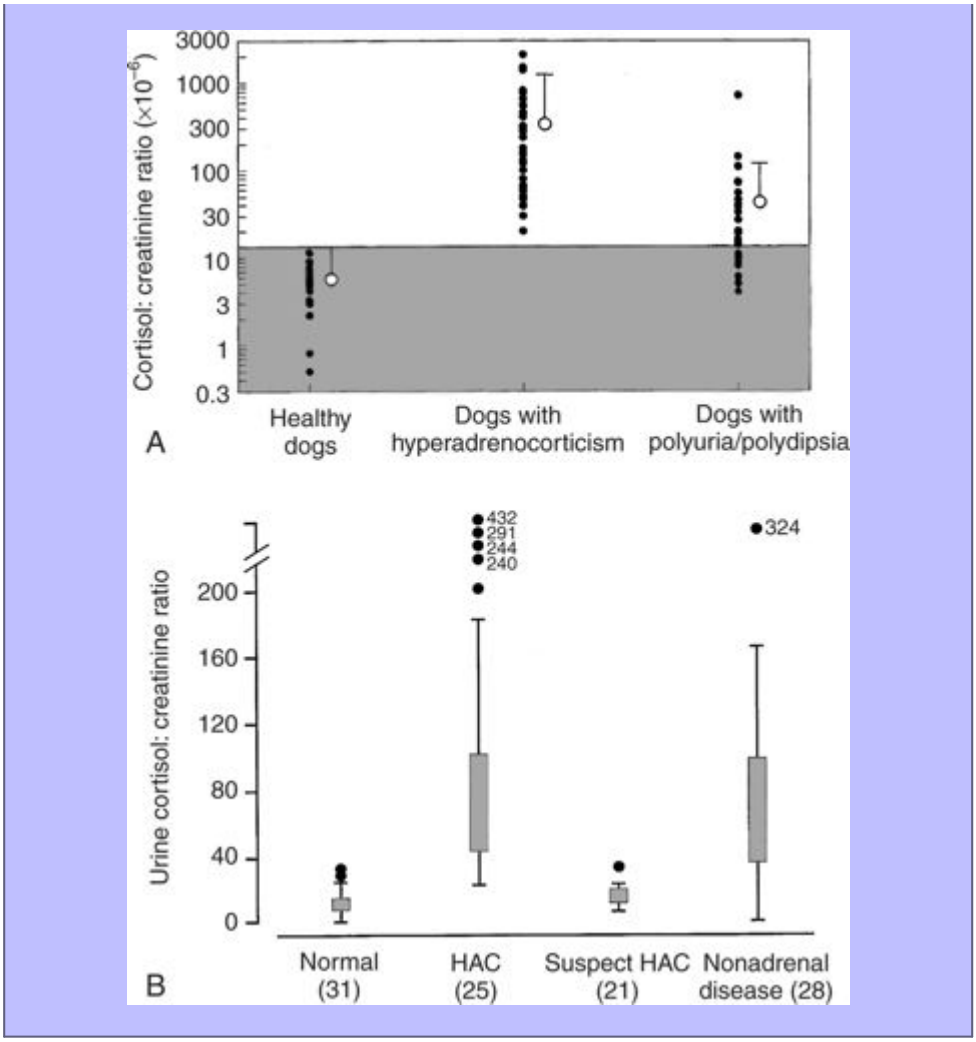
242.3.1.7.7.2

ACTH stimulation test

The ACTH stimulation test, which measures the response of the adrenal glands to maximal ACTH stimulation, is a test of adrenal gland reserve. The major function of this test is to diagnose or rule out hypoadrenocorticism. It has a sensitivity of 60% to 85% and a specificity of 85% to 90% (Figure 242-7). The sensitivity is higher (up to 85%) for the diagnosis of PDH than for the diagnosis of FAT (approximately 60%).[48] However, it is not possible to differentiate PDH from an FAT by means of the ACTH stimulation test on an individual case basis.

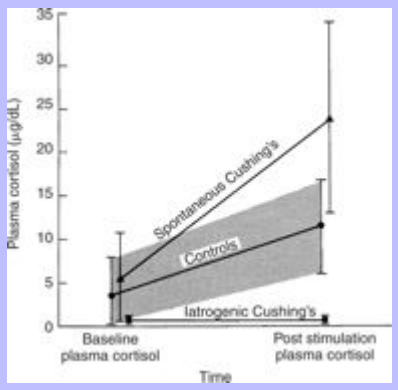
Several test protocols have been described that use either aqueous porcine ACTH gel (Acthar® Gel, Questcor Pharmaceuticals, Inc., Union City, USA; not available in certain countries) or a synthetic polypeptide containing the first 24 aminoacids of ACTH (Cortrosyn, Synacthen). Plasma samples are obtained before and 2 hours after intramuscular injection of 2.2 IU/kg of ACTH gel to determine the cortisol concentration. With the synthetic preparations, most protocols recommend collection of plasma before and 1 hour after intramuscular or intravenous[51] administration of 250 µg of synthetic ACTH. However, maximal stimulation of the adrenal glands can also be achieved with a dosage of 5 µg of synthetic ACTH per kilogram of body weight.[52] Reconstituted ACTH can be stored in plastic syringes at −20° C for 6 months.[53] The normal baseline cortisol concentration is 0.5 to 6 µg/dL, and the normal post-ACTH cortisol concentration is 6 to 17 µg/dL. Post-stimulation cortisol values between 17 and 22 µg/dL are considered borderline; values above 22 µg/dL are consistent with hyperadrenocorticism.

Figure 242-6 **A,** Urine cortisol to creatinine (C:C) ratios from healthy dogs, dogs with naturally occurring hyperadrenocorticism, and dogs with polyuria and polydipsia due to disorders other than hyperadrenocorticism. These values illustrate that the C:C ratio is a sensitive test for Cushing's syndrome, but it is not specific and should not be used as the sole test to confirm a diagnosis. **B,** Box plots of the urine C:C ratios found in normal dogs, dogs with hyperadrenocorticism (HAC), dogs in which hyperadrenocorticism initially was suspected but that did not have the disease (suspect HAC), and dogs with a variety of severe nonadrenal diseases. The number of dogs in each group is shown in parentheses. The box represents the interquartile range from the 25th to the 75th percentile (representing the middle half of the data). The horizontal bar through the box is the median. The "whiskers" represent the main body of data, which in most cases is equal to the range. Outlying data points are represented by the circles (exact values are given for these cases). These data illustrate that the urine C:C ratio is sensitive but not specific for the diagnosis of Cushing's syndrome. (**A** from Feldman EC, Mack RE: Urine cortisol: creatinine ratio as a screening test for hyperadrenocorticism in dogs. J Am Vet Med Assoc 200:1637, 1992; **B** from Smiley LE, Peterson ME: Evaluation of a urine cortisol: creatinine ratio as a screening test for hyperadrenocorticism in dogs. J Vet Intern Med 7:163, 1993.)



There are several reasons to use this test despite its relatively low sensitivity. First, it is the only test to differentiate between iatrogenic and naturally occurring hyperadrenocorticism. Second, because the test is frequently used to monitor medical therapy, it appears helpful to know the stimulation capacity of the adrenal glands prior to treatment. A possible third reason was recently revealed. It has been hypothesized that some dogs with hyperadrenocorticism that have normal ACTH stimulation results, in fact have a derangement of the steroid synthesis pathway; this would lead to abnormally increased precursor concentrations but normal concentrations of the end product, cortisol. Preliminary evaluations revealed that 17-hydroxprogesterone, one of the precursors, showed an exaggerated response to ACTH stimulation in dogs with Cushing's syndrome, which had abnormal or normal cortisol responses.[54] Further studies are needed to confirm whether the measurement of 17-hydroxprogesterone or other precursor concentrations is helpful in the diagnosis of canine Cushing's syndrome.

Figure 242-7 Mean radioimmunoassay (RIA) plasma cortisol concentrations (±2 SD) determined before and 1 hour after administration of synthetic ACTH in control dogs, dogs with spontaneous hyperadrenocorticism, and dogs with iatrogenic hyperadrenocorticism.



242.3.1.7.7.3 Low-dose dexamethasone suppression test

Dexamethasone is a synthetic glucocorticoid that does not cross-react with cortisol assays, therefore it can be used to evaluate the pituitary–adrenal gland axis. In normal dogs, the cortisol concentration decreases 2 to 3 hours after administration of dexamethasone and remains low for up to 24 to 48 hours. In dogs with hyperadrenocorticism, the pituitary–adrenal gland axis is abnormally resistant to the suppressive effects of dexamethasone and/or dexamethasone is metabolized more rapidly than normal. For the low-dose dexamethasone suppression (LDDS) test, blood samples are collected before and 4 and 8 hours after intravenous administration of dexamethasone at a dosage of 0.01 mg/kg. Either dexamethasone sodium phosphate or dexamethasone in polyethylene glycol may be used. In normal dogs the cortisol concentration is less than 1.4 μg/dL at 4 and 8 hours after dexamethasone administration. The cortisol concentration 8 hours after dexamethasone administration is used to detect hyperadrenocorticism; a concentration equal to or greater than 1.4 μg/dL is consistent with hyperadrenocorticism. The cortisol concentration at 4 and 8 hours after dexamethasone administration is also used as a differentiating test (see later). For the diagnosis of hyperadrenocorticism, the sensitivity of the test at 8 hours after dexamethasone administration is higher (85% to 95%) than the specificity (70% to 75%) (Figure 242-8).[48]

242.3.1.7.7.4 Misleading results

All three screening tests can have false-positive results in dogs suffering from nonadrenal disease,[55] therefore testing of such animals for hyperadrenocorticism should be avoided if possible. In general, a definitive diagnosis of hyperadrenocorticism should never be made solely on the basis of positive test results; the history and clinical findings should be considered carefully with each dog.

The extent to which phenobarbital treatment affects the results of screening tests is unclear. A review of the literature suggests that test results probably are not affected by this drug.

242.3.1.7.7.5 Glucocorticoid-induced alkaline phosphatase isoenzyme, liver biopsy, and combined dexamethasone suppression and ACTH stimulation tests

None of these tests give reliable results, therefore they are not recommended as screening tests for hyperadrenocorticism.

242.3.1.7.8 Differentiating tests

242.3.1.7.8.1 Extended low-dose dexamethasone suppression test

In dogs with an FAT, pituitary ACTH secretion is suppressed as a result of autonomous secretion of cortisol from the tumor. Administration of dexamethasone has no effect on the pituitary, and cortisol secretion therefore continues. Pituitary tumors have variable sensitivities to feedback inhibition, and the result is different response patterns after dexamethasone application.

The LDDS test can be used to identify dogs with PDH based on three criteria: a 4-hour cortisol concentration of less than 1.4 µg/dL; a 4-hour cortisol concentration of less than 50% of the basal cortisol concentration; and an 8-hour cortisol concentration of less than 50% of the basal cortisol concentration but equal to or greater than 1.4 µg/dL. When one or more of these criteria are met, the dog most likely has PDH.

Approximately 25% of dogs with PDH have a 4-hour cortisol concentration of less than 1.4 µg/dL; 60% have a 4-hour cortisol concentration of less than 50% of the basal concentration; and 25% have an 8-hour cortisol concentration of less than 50% of the baseline value. Overall, approximately 60% of dogs with PDH meet at least one of the three criteria. Dexamethasone resistance (none of the criteria are met) occurs in about 40% of dogs with PDH and in virtually all dogs with an FAT.[56] In such dogs another differentiating test must be used (see Figure 242-8).

A significant positive correlation was found between the size of the pituitary tumor and resistance to dexamethasone using the high-dose dexamethasone suppression test.[13] According to a preliminary study, similar results may be achieved with the LDDS test. Dogs with large pituitary tumors were significantly more often resistant to dexamethasone (according to the criteria cited above) than dogs with small tumors.[57]

242.3.1.7.8.2 High-dose dexamethasone suppression test

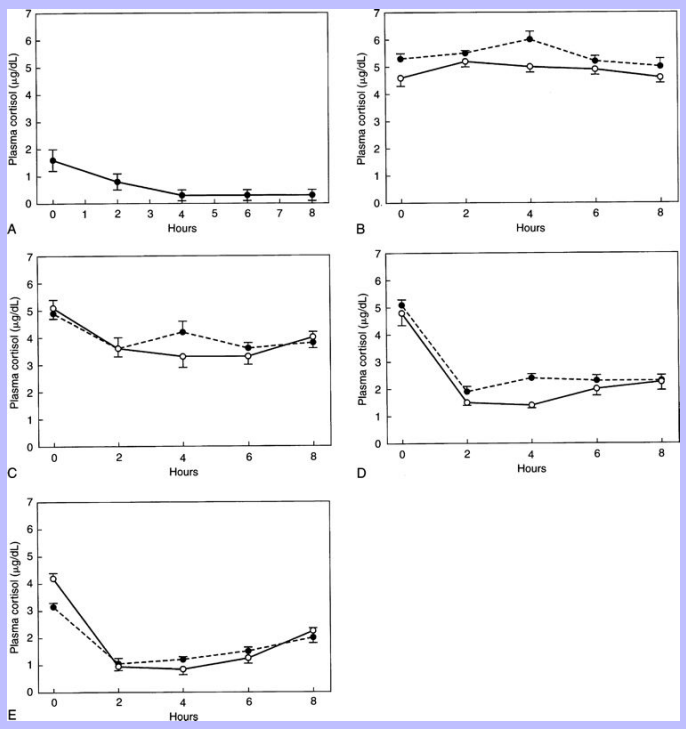
Traditionally, the high-dose dexamethasone suppression (HDDS) test has been used to differentiate PDH from an FAT. In dogs with an FAT, even large doses of dexamethasone should not suppress plasma cortisol levels. In contrast, administration of a large dose of dexamethasone should suppress ACTH secretion in most dogs with PDH. The test protocol is the same as that for the LDDS test except that a dexamethasone dosage of 0.1 mg/kg is used. Suppression is defined as a cortisol concentration less than 50% of the baseline concentration or less than 1.4 µg/dL at 4 or 8 hours after injection of dexamethasone. Suppression of the cortisol concentration occurs in approximately 75% of

dogs with PDH, whereas suppression virtually never occurs in dogs with an FAT. The HDDS test, therefore, is interpreted as follows: If the cortisol concentration is suppressed, a dog most likely has PDH; if no suppression of cortisol levels occurs, a dog may have either PDH or an FAT.

According to the results of one study,[13] if the cortisol concentration is not suppressed in the HDDS test, a dog with PDH may have large pituitary tumors.

Many dogs with PDH that show suppression of the cortisol concentration on the HDDS test also show cortisol suppression on the LDDS test. In one large study,[56] the HDDS test results provided additional information in only a small percentage of dogs (26 of 216 [12%]). It therefore appears useful routinely to perform an extended LDDS test in dogs suspected of having Cushing's syndrome. In dogs with dexamethasone resistance, rather than a HDDS test, it probably would be more efficient to perform one of the other differentiating tests, such as measurement of endogenous ACTH or adrenal ultrasonography.

Figure 242-8 Mean plasma cortisol concentrations before and after administration of a low dose of dexamethasone in (**A)** 27 normal dogs; **(B)** 48 dogs with adrenocortical tumors; **(C)** 130 dogs with pituitary-dependent hyperadrenocorticism (PDH); **(D)** the dogs among the 178 with Cushing's syndrome that had at least one plasma cortisol concentration less than 1.4 µg/dL after dexamethasone administration (total, 54; each had PDH); and **(E)** the dogs among the 178 with Cushing's syndrome that, after dexamethasone administration, had at least one plasma cortisol concentration less than 50% of the baseline concentration (total, 95; each had PDH). Note the two curves for graphs **B, C, D,** and **E.** These represent the use of dexamethasone sodium phosphate *(dashed line)* and dexamethasone in polyethylene glycol *(solid line)*. No significant difference in results is seen with these dexamethasone products. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 2nd ed. Philadelphia, WB Saunders, 1996, p 227.)



242.3.1.7.8.3

Extended urine cortisol to creatinine ratio

The extended urine C:C ratio combines a screening test (urine C:C ratio) with a differentiating test (a special form of the HDDS test). Urine samples are collected at home for 3 consecutive days for determination of the C:C ratio. After the second urine sample has been collected, the owner administers 0.1 mg/kg of dexamethasone, per os, at 8-hour intervals (three times). The mean is calculated from the first two urine samples and is used as baseline urine C:C ratio. Provided the baseline urine C:C ratio is elevated, a diagnosis of PDH is justified if the ratio of the third sample is less than 50% of the baseline value.[17]

The advantage of this test is that it can be performed at home. Disadvantages include the limited specificity of the urine C:C ratio and possible owner error associated with administration of the dexamethasone tablets. Little current information is available regarding the accuracy of this test.

242.3.1.7.8.4

Endogenous ACTH

Determination of the ACTH concentration is a reliable test for differentiating PDH from an FAT. In dogs with an FAT, the ACTH concentration is suppressed through negative feedback, whereas in dogs with PDH, the pituitary tumor secretes ACTH. Rapid processing of the sample is important because the hormone disappears quickly from fresh whole blood. Blood should be collected into a chilled plastic tube containing ethylenediamine tetra-acetic acid (EDTA) and immediately centrifuged at 4° C. The plasma should be stored at −20° to −70° C, then packed on dry ice and shipped to a laboratory. Addition of the protease inhibitor aprotinin (500 kallikrein inactivator units per milliliter of blood) to the EDTA tube may prevent rapid breakdown of ACTH.[58] Not all assays for human ACTH can be used in the dog, therefore validation is imperative.

The reference range for ACTH is 20 to 100 pg/mL. Concentrations of ACTH less than 20 pg/mL are strongly suggestive of an FAT, and concentrations greater than 45 pg/mL are consistent with a diagnosis of PDH. The range between 20 and 45 pg/mL is considered nondiagnostic. It should be noted that reference ranges and cutoff values may differ among laboratories. In one study, approximately 70% of dogs with an FAT had ACTH concentrations less than 20 pg/mL; in the remaining dogs, the ACTH concentration was in the nondiagnostic range.[24] In another study, 85% to 90% of dogs with PDH had ACTH concentrations greater than 45 pg/mL, and in the remaining 10% to 15%, the levels were nondiagnostic.[59] In dogs with a nondiagnostic test result, another sample should be submitted or another differentiating test performed (Figure 242-9).

242.3.1.7.8.5

Ultrasonographic examination of the adrenal glands

Adrenal ultrasonography is an extremely valuable tool for differentiating PDH from an FAT (see Ultrasonography, above).

242.3.1.7.9

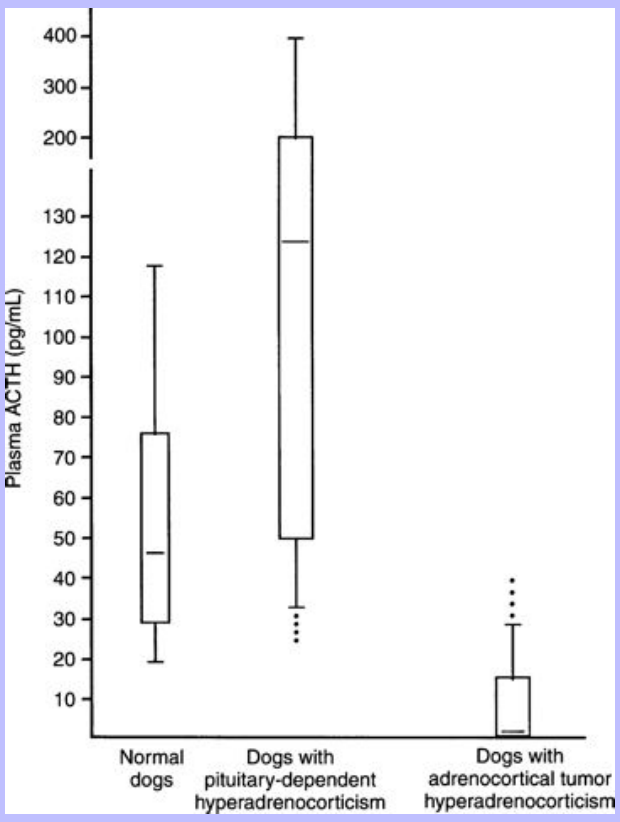
Advanced diagnostic imaging

Because the adrenal glands can be visualized so well with ultrasonography, advanced imaging techniques usually are not required. However, techniques such as CT and MRI are the only reliable

methods of evaluating the size of a pituitary tumor. Survey radiography of the skull does not aid in their diagnosis because pituitary tumors in dogs usually do not erode bone or invade the sphenoid bone.

Because the pituitary lacks a complete blood-brain barrier, contrast medium diffuses freely from the circulation into the interstitial space. Contrast enhancement of a pituitary tumor improves its detection and allows delineation of tumor from peritumoral edema and adjacent neural structures.

Figure 242-9 Endogenous plasma ACTH concentrations from clinically normal dogs, dogs with functioning adrenocortical carcinomas or adenomas, and dogs with pituitary-dependent hyperadrenocorticism (PDH). Each box represents the interquartile range from the 25th to the 75th percentile (the middle half of the data). The horizontal bar through the box is the median. The "whiskers" represent the main body of data, which in most cases is equal to the range. Outlying data points are represented by the circles. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 2nd ed. Philadelphia, WB Saunders, 1996, p 230.)



In dogs, pituitary tumors grow dorsally. The so-called suprasellar tumor extension is partly a reflection of the incomplete diaphragma sella, which provides minimal resistance. Growth may result in invagination into the third ventricle, and the tumor may eventually compress and/or invade the hypothalamus and thalamus and, when large enough, other brain structures. In contrast to humans with pituitary tumors, the optic chiasm in dogs is usually spared because of its more rostral location.

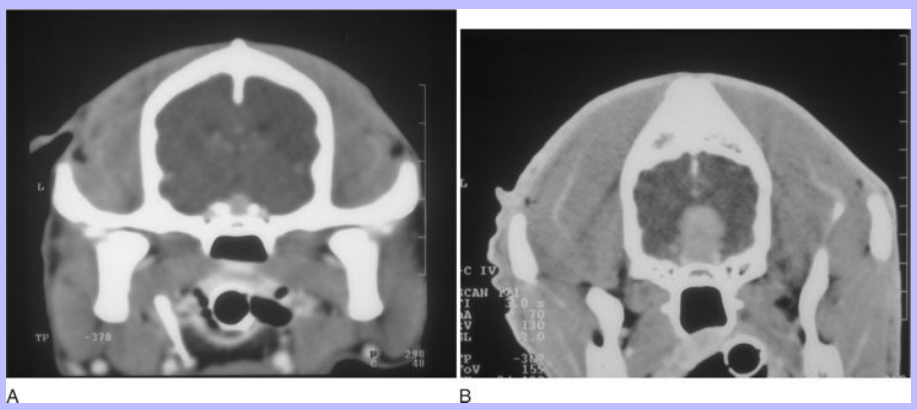
Currently we recommend that CT (or MRI) be performed in dogs with PDH because of the potential risk of a large tumor (see below). However, CT and MRI cannot replace endocrine function tests, because about half of pituitary tumors are not visible. In addition, CT and MRI do not differentiate between a functional and nonfunctional mass (Figures 242-10 and 242-11).

242.3.1.7.9.1

Computed tomography

The size of the pituitary gland varies among different breeds of dogs and among dogs of the same breed. In 35 healthy dogs, CT measurements of the pituitary gland ranged from 3.2 to 5.1 mm for height, 4.2 to 6.9 mm for width, and 3.6 to 7.2 mm for length.[60] The first sign of pituitary enlargement appears to be an increase in height (i.e., dorsal extension into the suprasellar region). The pituitary gland is considered to be enlarged when the dorsal contour of the pituitary protrudes above the suprasellar extension of the intercrural cisterns, which are easily recognized on CT images.[13] Alternatively, the ratio of the height of the pituitary gland to the area of the brain measured on an image through the center of the pituitary (P:B ratio) can be used to discriminate between enlarged (P:B greater than 0.31) and normal (P:B less than or equal to 0.31) pituitary glands.[60] Large tumors are easily detected on contrast-enhanced CT images because of their size and altered shape. In rare cases, tumors may be difficult to visualize without contrast. In 50% to 60% of dogs with PDH, a pituitary mass can be detected by CT. In the remaining 40% to 50% of cases, the disease is caused by a small tumor (less than 3 to 4 mm) that is not visible even with contrast. Newer CT techniques, using a series of transverse scans through the center of the pituitary during and after rapid intravenous injection of contrast medium (dynamic CT), reveal a difference in enhancement between the neurohypophysis and the adenohypophysis. This is due to variations in the blood supply; an early, strong enhancement of the central neurohypophysis (“pituitary flush”) is seen, as is a slightly delayed, weaker enhancement of the peripheral adenohypophysis. Displacement or distortion of the neurohypophyseal flush may reveal the existence of small tumors.[61]

Figure 242-10 Contrast-enhanced transverse computed tomographic images through the pituitary. **A,** Mixed-breed dog with signs of hyperadrenocorticism but no neurologic signs. The pituitary is enlarged (0.6 cm in height). **B,** Bergamasker with hyperadrenocorticism that had been treated with mitotane for 2 years, after which neurologic signs developed (i.e., disorientation, ataxia, aggressive behavior). The pituitary is grossly enlarged (2.1 cm in height).



242.3.1.7.9.2 Magnetic resonance imaging

Although CT and MRI are both effective at identifying large pituitary tumors, MRI is superior for defining the full extent and relationship of a tumor to surrounding structures and is probably more accurate in identifying small lesions. The size, signal, and contrast enhancement characteristics of the normal canine pituitary gland using MRI have been described.[62] In one study, in about 50% of dogs with PDH and no neurologic signs, a pituitary tumor was visible on MRI, and the tumors ranged in size from 4 to 12 mm.[63]

242.3.1.8 Treatment

The method of treatment must be carefully chosen based on the cause of the disease (PDH or an FAT), the age and condition of the dog, and whether concomitant disease is a factor. The cost and availability of treatment methods, as well as the frequency of follow-up evaluations, are also important considerations.

242.3.1.9 Surgery

242.3.1.9.1 Adrenal tumor

Surgical removal is the treatment of choice for adrenal tumors. Each dog must be assessed preoperatively for metastases or invasion of the tumor into surrounding tissues. Adrenalectomy is technically challenging and should be performed by a skilled surgeon. Approximately 50% of dogs develop severe postoperative complications, including pancreatitis, pneumonia, pulmonary thromboembolism, acute renal failure, sepsis, and hypoadrenocorticism due to insufficient steroid levels. The reported death rate after adrenalectomy varies greatly; in two large studies the rate was 27% and 34%.[19,26] It is not known whether dogs with an FAT that undergo long-term medical treatment before adrenalectomy have fewer postoperative complications and higher survival rates. In dogs in which tumor removal was incomplete, clinical signs persist, or hyperadrenocorticism recurs weeks to months after surgery.

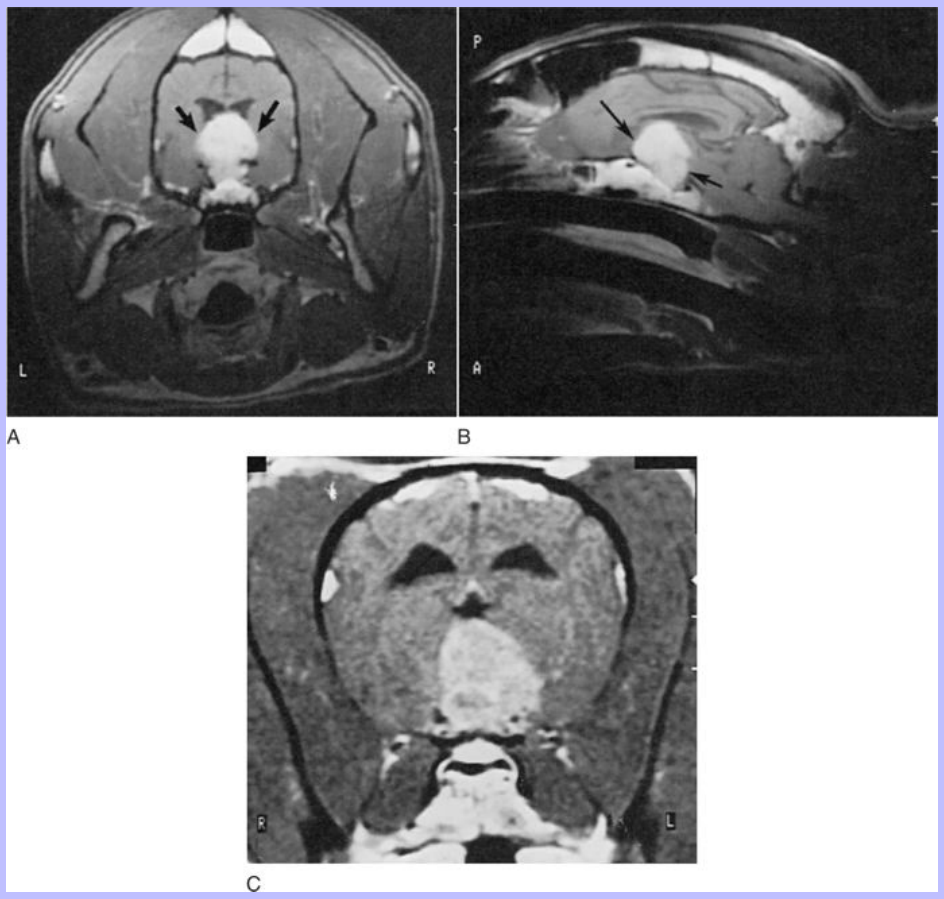
Autonomous cortisol secretion results in atrophy of the cells of the zona fasciculata and zona reticularis and, in a few dogs, of the aldosterone-producing cells of the zona glomerulosa. Thus glucocorticoid substitution intraoperatively and postoperatively is necessary. Mineralocorticoid treatment is instituted when required.

Intravenous fluids (0.9% sodium chloride [NaCl] or Ringer's solution) should be administered at a maintenance rate at the start of anesthesia and during surgery and the postoperative period. When the tumor is located, dexamethasone should be given at a dosage of 0.1 mg/kg over a 6-hour period. The dose should be repeated two to four times per day, subcutaneously, until oral medication can be started.[59] An alternative to dexamethasone is hydrocortisone, which can be given intravenously during surgery at a dosage of 4 to 5 mg/kg, and thereafter at a dosage of 1 mg/kg given intravenously every 6 hours until oral medication is started. Compared to dexamethasone, hydrocortisone has the advantage of having both glucocorticoid and mineralocorticoid activity. Prednisolone is then administered orally according to the following schedule:

1603 1604

- 1 mg/kg twice daily for 2 to 3 days
- 0.5 mg/kg twice daily for 2 to 3 days
- 0.25 mg/kg twice daily for 3 weeks
- 0.25 mg/kg once a day for 3 weeks
- 0.25 mg/kg every other day for 3 weeks
- 0.25 mg/kg every 3 days

Figure 242-11 **A,** Transverse view of a post-gadolinium MRI scan of a 7-year-old bull terrier with pituitary-dependent hyperadrenocorticism (PDH) caused by a 2.4 cm mass *(arrows);* the dog developed signs of disorientation and ataxia. **B,** Midline sagittal view of the brain of the same dog (using MRI), showing the densely enhancing mass *(arrows)* arising from the pituitary fossa and causing compression of the floor of the overlying third ventricle. **C,** Post-gadolinium MRI scan of an 8-year-old Boston terrier with PDH and signs of disorientation, ataxia, and circling. (From Feldman EC, Nelson RW: Canine and Feline Endocrinology and Reproduction, 2nd ed. Philadelphia, WB Saunders, 1996, p 237.)



Prednisolone usually can be discontinued after 2 to 3 months. The ACTH stimulation test is helpful for evaluating adrenal function. Intensive postoperative monitoring is essential for preventing or detecting potential complications. If hyperkalemia and/or hyponatremia occur, oral fludrocortisone (0.01 to 0.02 mg/kg/day) or parenteral desoxycorticosterone pivalate (DOCP; 2.2 mg/kg every 25 days) should be given. In most cases these electrolyte abnormalities, which reflect mineralocorticoid deficiency, last only a few days. Antibiotics, pain medication, and heparin should be used routinely. When bilateral adrenalectomy is performed (because of bilateral tumors), the dog needs lifelong supplementation with mineralocorticoids and glucocorticoids. 1604

1605

242.3.1.9.2 Pituitary tumor

242.3.1.9.2.1 Hypophysectomy

During the past decade, transsphenoidal pituitary surgery has become the treatment of choice for humans with PDH. Although hypophysectomy has been attempted numerous times in dogs, the procedure has only recently become feasible.[60,64] Hypophysectomy in dogs (and cats) is performed by a transsphenoidal approach. Of 84 dogs with PDH that underwent hypophysectomy,[65] six died within 4 weeks of surgery and were considered procedure-related mortalities. In another six dogs, the tumor was incompletely removed. The overall response rate was 86% (i.e., 72 of the 84 dogs went into remission). This compares favorably with the results of dogs with PDH treated medically with mitotane. Perioperative and long-term complications include mild transient hypernatremia, transient reduction or cessation of tear production, diabetes insipidus (persistent in 10% of cases), and secondary hypothyroidism (persistent in all cases). Hyperadrenocorticism recurred in 11 of 72 dogs (15%), 5 to 47 months after surgery. Thus far, only dogs with small or moderate-sized tumors (up to 10 mm in diameter) have been suitable candidates.

Pituitary surgery is possible only in a specialized veterinary institution and requires a team approach involving a neurosurgeon, an endocrinologist, and a radiologist.[65] Transsphenoidal hypophysectomy has the potential to become the treatment of choice for dogs (and cats) with PDH.

242.3.1.9.2.2 Adrenalectomy

Removal of both adrenal glands results in complete resolution of the clinical signs of hyperadrenocorticism. However, because the success rate of medical treatment is relatively high and treatment is fairly easy, the risk of surgery seems unwarranted.

242.3.1.10 Medical Management

Medical management of dogs with Cushing's disease may be questioned, because unlike adrenalectomy or hypophysectomy, it does not result in a cure. No studies have investigated the degree to which medical treatment increases the life expectancy of dogs with Cushing's syndrome. However, uncontrolled hyperadrenocorticism markedly affects the quality of life and can lead to a number of complications, including infection and life-threatening thromboembolism. For these reasons, treatment should be undertaken in most dogs with clinical signs of hyperadrenocorticism. Exceptions include very old dogs and those with concomitant disease in which appetite is sustained by excess cortisol. Dogs with laboratory values consistent with hyperadrenocorticism (increased ALP, positive screening test results) but without

clinical signs should not be treated. In cases in which the cause of the abnormal test results (e.g., primary hepatopathy) remains unknown, the dog should be re-evaluated a few weeks or months later.

Mitotane, trilostane and, to a lesser extent, ketoconazole are effective treatments for hyperadrenocorticism.

242.3.1.10.1 Mitotane

Mitotane (o, p'-DDD, Lysodren) is a potent adrenocorticolytic drug that causes necrosis of the zona fasciculata and zona reticularis (sites of glucocorticoid production). The zona glomerulosa (site of mineralocorticoid production) is less sensitive to this drug. Mitotane is fat soluble and should always be administered with a meal.

Depending on the dosage and duration of treatment, the adrenal cortex may be partly or completely destroyed. Currently, two main treatment regimens are based on this pretext.

242.3.1.10.2 Partial adrenocortical destruction

The goal of this treatment regimen is to partly destroy the zona fasciculata and zona reticularis so that excess cortisol production is stopped and synthesis is restricted to amounts needed for daily life. The zona glomerulosa should retain all of its function. Treatment consists of an induction phase and a maintenance phase.

242.3.1.10.2.1 Induction phase

For induction, mitotane is administered at a dosage of 50 mg/kg/day, divided, given twice a day at the end of a meal. It is difficult to determine when adrenocortical destruction is adequate to prevent the occurrence of hypoadrenocorticism by further treatment. Daily administration of mitotane should be stopped when (1) the dog's water intake decreases markedly; (2) the dog's appetite is reduced or the dog eats more slowly (thus the meal is offered before administration of mitotane); or (3) the dog has vomiting, diarrhea, or lethargy. For most dogs with Cushing's syndrome, a change in appetite is the most reliable indicator of effective treatment. When a change in the dog's appetite is noted, re-evaluation by the veterinarian and an ACTH stimulation test should be performed. Treatment is considered adequate when the post-ACTH plasma cortisol concentration is 1 to 4 μg/dL. The time required to achieve this varies among dogs. The average length of induction reported in the literature differs. We found that the target concentration of cortisol was achieved after 3 to 4 days of therapy in more than 50% of dogs with PDH.[66] Thus we routinely perform an ACTH stimulation test on the fifth day of treatment. When the post-ACTH plasma cortisol concentration is 1 to 5 μg/dL, maintenance therapy is started. Some dogs may need 1 or more days of induction therapy, and a second ACTH stimulation test may be required.

Another method of monitoring treatment involves daily phone calls by the veterinarian to the owner regarding the dog's condition, particularly appetite.[59] Appetite is the most important aspect of the monitoring of the response to treatment. Dogs with a poor appetite before the start of treatment should be carefully reassessed; either they do not have Cushing's syndrome, or they have concurrent disease, which must be treated first.

Even with careful treatment and monitoring, some dogs experience apathy, weakness, anorexia, vomiting, diarrhea, and/or ataxia. These symptoms may be due to (1) lower than normal plasma

cortisol concentrations (overdose), (2) a decrease in plasma cortisol levels to within the normal range (relative glucocorticoid deficiency, or *glucocorticoid withdrawal syndrome*); or (3) mitotane intolerance. With these dogs, owners are told to stop mitotane treatment and to administer prednisolone (or prednisone) at a dosage of 2 mg/kg per os. When the symptoms are attributable to decreased cortisol levels, dogs return to normal within a few hours. An ACTH stimulation test should be performed to differentiate overdose of mitotane from glucocorticoid withdrawal syndrome. In dogs with mitotane overdose (i.e., a post-ACTH cortisol level of less than 1 μg/dL), prednisolone is administered and tapered over 1 to 3 weeks. If the dog's condition is then stable without prednisolone, mitotane treatment can be restarted at a maintenance dosage. In dogs that do not tolerate mitotane, the daily dosage can be divided into smaller portions, or another drug can be used.

A few researchers advocate administration of both mitotane and prednisolone during the induction phase. We feel that mitotane overdose can be more rapidly recognized clinically when that drug is used alone.

242.3.1.10.2.2

Maintenance phase

Maintenance therapy starts with administration of about 50 mg/kg of mitotane per week (e.g., given on Wednesday and Sunday); the dose should be divided and given with meals. With time the dosage may need to be altered (some dogs require half the dose; others, double), therefore owners must be told to monitor the dog for signs of hypoadrenocorticism or recurrence of Cushing's symptoms. An ACTH stimulation test should be performed every 1 to 3 months during the early stages of maintenance treatment and then twice yearly. The goal of maintenance therapy is the same as that for induction: a post-ACTH plasma cortisol concentration of 1 to 5 μl/dL. Determination of the urine C:C ratio is not suitable for monitoring treatment, because overlap occurs between well-regulated and overdosed patients.

1605

1606

Mitotane overdosage may occur at any time during treatment and usually manifests as a glucocorticoid deficiency. Rarely, a concomitant mineralocorticoid deficiency with electrolyte abnormalities may be seen. Treatment consists of cessation of mitotane therapy (transient in most cases) and administration of prednisolone. In dogs with complete adrenocortical insufficiency, a mineralocorticoid (fludrocortisone or DOCP) must also be administered. Permanent adrenocortical insufficiency rarely occurs and is seen in about 5% of cases. In a small number of dogs, mitotane induces CNS symptoms, such as apathy, ataxia, blindness, and head pressing. These clinical signs usually occur several months after the start of treatment and, because of their transient nature, disappear a few hours after administration of the drug. Dividing the dosage over multiple administrations is often helpful, but in some cases the dosage must be reduced. Similar symptoms occur with mitotane overdosage or an expanding hypophyseal tumor, therefore careful re-evaluation of the patient is required.

Approximately 50% of dogs have recurrence of symptoms at some point during treatment. The reasons are similar to those for recurrence during the induction phase: (1) the individual animal requires a higher dosage; (2) owner compliance is poor; (3) the drug is not given with food and thus is poorly absorbed; (4) a drug-associated decrease in intestinal fat absorption results in decreased mitotane absorption; (5) the dog has an FAT rather than PDH; (6) increased ACTH secretion by the hypophyseal tumor (possibly supported by a decrease in negative feedback) results in regeneration of the adrenal cortex; and (7) mitotane stimulates induction of microsomal liver enzymes for its own metabolism.

The partial adrenocortical destruction regimen results in a good to excellent response in about 80% of dogs with PDH. It can also be used to treat dogs with an FAT. It is important to remember that compared to hyperplastic cells, tumor cells frequently are more resistant to the cytotoxic effects of mitotane. About 50% of dogs with an FAT require an induction phase lasting longer than 2 weeks. On average, they also require a higher maintenance dosage of mitotane.[67] Because approximately 50% of dogs with an FAT have adrenal carcinomas, we use the following treatment regimen in those that do not undergo adrenalectomy.

242.3.1.10.2.3

Complete adrenocortical destruction

The goal of this treatment regimen is destruction of the entire adrenal cortex, with resultant iatrogenic hypoadrenocorticism, by long-term mitotane administration.[68]

Mitotane is administered at a dosage of 50 to 75 mg/kg/day (divided into three or four smaller doses given with food) for 25 days. Lifelong administration of fludrocortisone (0.01 mg/kg) and cortisone is started on the third day of mitotane administration. The cortisone dosage is 1 mg/kg given twice a day; then, 1 week after the discontinuation of mitotane treatment, the cortisone dosage is reduced to 0.5 mg/kg given twice a day. An equivalent dose of prednisolone (approximately 0.4 mg/kg and then 0.2 mg/kg) can be used instead of cortisone, because it is less expensive. In a number of dogs, daily mitotane administration must be stopped for a short period because of adverse side effects, such as anorexia, vomiting, diarrhea, weakness, and neurologic symptoms. In most dogs, mitotane administration can be resumed after a few days. This treatment regimen is easier to implement than that for partial adrenocortical destruction because it is not necessary to determine when the therapy takes effect. The side effects and complications are similar to those of other regimens using mitotane. However, the risk of unrecognized adrenal insufficiency is lower, because cortisone and mineralocorticoids are substituted.

The necessity of administering daily medication to prevent life-threatening hypoadrenocorticism must be emphasized to owners. The complete adrenocortical destruction regimen should be used only when the diagnosis is certain and owner compliance can be assured. Recurrence of initial symptoms can also occur with this regimen, therefore an ACTH stimulation test should be performed regularly (two to four times a year). Routine electrolyte evaluation (sodium, potassium) is recommended as for dogs with spontaneous Addison's disease. Clinical remission is reported to occur in 86% of dogs with PDH.[69]

We use complete adrenocortical destruction almost exclusively in dogs with inoperable adrenal tumors. In some dogs, this treatment regimen results in complete tumor remission and disappearance of metastases. For these patients, a modified treatment regimen is used: after the 25th day of daily therapy, mitotane is administered at a dosage of 50 to 75 mg/kg, given weekly (divided over two to four days) for life. An ACTH stimulation test is used routinely to ensure complete cessation of cortisol production, as indicated by a pre-ACTH and post-ACTH plasma cortisol concentration below the assay detection level.

For both protocols, the cortisol requirement in times of stress (illness, surgery) is increased and higher than the partly destroyed adrenocortex can produce or that is administered exogenously. Depending on the level of stress, up to 2 mg/kg of prednisolone may be given daily.

242.3.1.10.3 Trilostane

The use of trilostane for the treatment of canine PDH was first reported in 1998.[70] Since then the drug has gained wide popularity, especially in Europe. Two prospective studies that evaluated the effects of trilostane were recently published.[71,72] In the United Kingdom, trilostane is officially registered for use in dogs under the name of Vetoryl. The human preparation is available as Modrenal. Trilostane is an orally administered competitive inhibitor of 3-beta-hydroxysteroid dehydrogenase. This enzyme system mediates the conversion of pregnenolone to progesterone in the adrenal gland. Cortisol, aldosterone, and androstenedione are produced from progesterone via various biochemical pathways. Trilostane inhibits progesterone and blocks the synthesis of its end products (Figure 242-12).

We have used trilostane for nearly 4 years in the treatment of PDH and have found that about 80% of dogs have a good to excellent response. The time required for a noticeable response to trilostane is similar to that for mitotane. Improvements include a rapid decrease in polydipsia, polyuria, and polyphagia and a rapid increase in activity level, as well as delayed improvement in the haircoat, skin condition, and abdominal muscle tone. Some dogs may show transient worsening of dermatologic problems before clinical improvement becomes obvious; this may also occur with mitotane. The ACTH stimulation test determines adrenal reserve and therefore is suitable for evaluating the extent of enzyme inhibition during treatment and for calculating dosage adjustments (Figure 242-13).

We currently administer trilostane as follows: dogs weighing less than 5 kg receive 30 mg once a day; those weighing 5 to 20 kg receive 60 mg once a day; and those weighing more than 20 kg receive 120 mg once a day. Re-evaluations, which are performed after 1, 3, 6, and 13 weeks and 6 and 12 months, include the history, a physical examination, and an ACTH stimulation test. It appears important that, for each evaluation, testing be performed at the same time after drug administration. When the ACTH stimulation test is performed 2 to 6 hours after drug administration, the target range of the post-ACTH cortisol level is 1 to 2 µg/dL; this corresponds with the low end of the desired range for dogs treated with mitotane. Several of our dogs had post-ACTH cortisol levels between 0.5 and 1 µg/dL for months without showing signs of hypoadrenocorticism. Two explanations for this may be that (1) trilostane is known to decrease the cortisol concentration for only a few hours; and (2) steroid precursors, which have accumulated as a result of enzyme inhibition, may have certain glucocorticoid-like effects that prevent signs of hypocortisolism even when the cortisol concentration is low.

1606

1608

Figure 242-12 Biosynthetic pathways of mineralocorticoids, corticosteroids, and androgens in the adrenal cortex. *3β-HSD,* 3β-Hydroxysteroid dehydrogenase, which converts pregnenolone to progesterone and dehydroepiandrosterone to androstenedione. This enzyme system is blocked by trilostane.

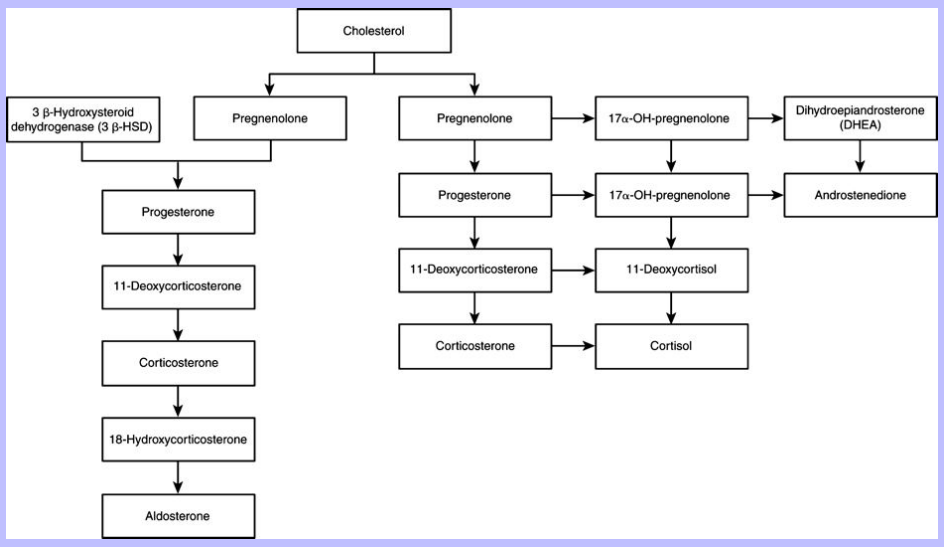


Figure 242-13 Cortisol concentrations after ACTH stimulation in dogs with PDH treated with trilostane. *0,* Prior to therapy; *1* to *5,* re-evaluations at 1, 3 to 4, 6 to 7, 12 to 16 and 24 to 28 weeks after initiation of treatment with trilostane. Data are presented as box plots; the boxes represent values from the 25th to the 75 percentile, the horizontal line in each box is the median, and the "whiskers" represent the range. (From Ruckstuhl NS et al: Results of clinical examinations, laboratory tests, and ultrasonography in dogs with pituitary-dependent hyperadrenocorticism treated with trilostane. Am J Vet Res 63:506–512, 2002.)

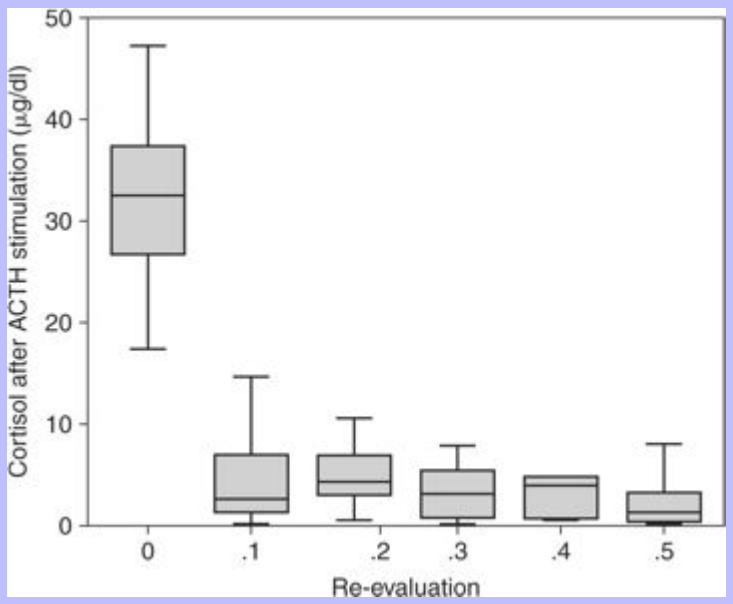

Frequent adjustments in the dosage of trilostane (both increases and decreases) are required, particularly during the first few weeks of treatment. Adjustments should be made in increments of 20 to 30 mg/dog. The effective dosage of trilostane differs markedly among dogs with PDH, possibly because of a significant variation among individuals in 3-beta-hydroxysteroid dehydrogenase activity in the adrenal glands. However, the response to treatment appears to stabilize over a period of time, after which dosage adjustments are seldom necessary.

Distinct changes in the ultrasonographic appearance of the adrenal glands were observed in our studies. In almost all dogs, a marked increase was seen in the thickness and echogenicity of the outer zone, which was assumed to be the adrenal cortex. This finding may reflect increased synthesis of precursors arising from an increase in ACTH secretion, or it may be the result of abolition of negative feedback normally exerted by cortisol. Studies are under way to verify this.

Overdosage of trilostane is possible and was assumed to be the cause of adverse symptoms in four of 88 dogs.[71,72] Three of the dogs survived with discontinuation of trilostane and institution of symptomatic treatment. Other problems attributed to the use of trilostane are rare and include lethargy, anorexia, vomiting, and diarrhea. These symptoms are usually mild and self-limiting. In a study of 78 dogs treated with trilostane,[72] it was not known whether the death of two dogs shortly after the start of treatment was related to the drug or to another illness. Postmortem examination of one dog revealed signs suggestive of terminal heart failure.

Our experience with trilostane is limited to treatment of canine PDH, which has entirely replaced mitotane at our hospital. It has been reported that trilostane can also effectively control hyperadrenocorticism caused by an FAT.

242.3.1.10.4 Ketoconazole

Ketoconazole, a fungistatic drug, also blocks several P-450 enzyme systems, effectively inhibiting the synthesis of glucocorticoids and androgens. Its effects on mineralocorticoids are negligible. Dogs are started at a dosage of 5 mg/kg given twice a day for 1 week. If the drug is well tolerated (i.e., no decrease in appetite or icterus is seen), the dosage is increased to 10 mg/kg given twice a day for 2 weeks. After this period, an ACTH stimulation test is performed. If the post-ACTH cortisol concentration is higher than the target range of 1 to 4 μg/dL, the dose should be increased to 15 mg/kg twice a day. Most dogs require a daily dose of 30 mg/kg for a long period for good clinical control. The disadvantages of ketoconazole are the expense, the requirement for twice daily administration for life, and the drug's lack of efficacy in up to 50% of cases. Possible side effects include anorexia, diarrhea, and increased hepatic enzyme activity. Hypocortisolism can also occur, but dogs respond rapidly to cessation of ketoconazole administration and administration of glucocorticoids. Before the introduction of trilostane, ketoconazole was primarily used in dogs that did not tolerate mitotane. Today, trilostane rather than ketoconazole would be chosen for such cases.

242.3.1.10.5 Selegiline hydrochloride

The use of selegiline hydrochloride (L-deprenyl) for the treatment of hyperadrenocorticism in dogs is controversial. L-deprenyl has been hypothesized to downregulate ACTH by enhancing the dopamine concentration, thereby controlling pituitary hyperadrenocorticism. For a number of years, various reports have described the efficacy of L-deprenyl in dogs with PDH, and aggressive advertising campaigns have been mounted. Interestingly, no scientific data were presented to substantiate these claims. A 6-month controlled clinical study revealed that of 10 dogs with PDH, treatment with L-deprenyl resulted in no clinical improvement in four dogs, worsening of symptoms in four others, and improvement in two. Several of the owners reported that dogs were more lively during treatment; this was assumed to be one reason for good owner compliance and for the improvement reported in the other studies. In those studies, evaluation of clinical signs was based on owner observations and not on scientific data. L-deprenyl is metabolized into substances with amphetamine-like structures, which may explain the improvement in the general condition and behavior of treated dogs. We do not recommend L-deprenyl for the treatment of canine PDH.[73]

242.3.1.10.6 Other drugs

A variety of other drugs (bromocriptine, cyproheptadine, metyrapone, aminoglutethimide) have been investigated for the treatment of hyperadrenocorticism; however, they have not produced favorable results.

242.3.1.11 Complications and Concurrent Disease Associated with Hyperadrenocorticism

242.3.1.11.1 Large pituitary tumors

Generally, dogs with PDH have a risk of pituitary tumor growth. Approximately 50% of dogs with PDH have a tumor that is visible on CT or MRI scans at the time of diagnosis, and in approximately 50% of all dogs with PDH, the tumor has a tendency to grow. Neurologic signs caused by expansion of a pituitary tumor are seen in about 15% to 20% of dogs with PDH.[74–76]

1608

1609

Hypophyseal tumors are often categorized, according to their size, as macrotumors (equal to or greater than 10 mm in height) or microtumors (less than 10 mm in height). However, this categorization is useful for neither clinical nor imaging purposes. Tumors as small as 3 to 4 mm can be visualized using advanced imaging techniques. Neurologic symptoms occur in some dogs with tumors less than 10 mm but may not occur in others with tumors 10 mm or larger. It would appear more appropriate to use the term *macrotumor* to describe tumors visible by means of CT or MRI and the term *microtumor* to define masses that cannot be visualized. Pituitary tumors grow dorsally in the dog. The diversity of neurologic signs is due to involvement of different regions of the hypothalamus and thalamus and other brain regions.

The onset of neurologic signs may precede, coincide with, or follow (most often in clinical practice) the diagnosis of hyperadrenocorticism. Clinical signs are usually quite subtle at the start and can be recognized only by someone who knows the dog well. In most cases these signs constitute slight changes in the dog's behavior. Symptoms progress slowly to include dullness, listlessness, restlessness, loss of interest in normal activities, brief episodes of disorientation, anorexia, and weight loss. Later in the course of the disease, symptoms include ataxia, aimless pacing, and stupor. Some dogs may be misdiagnosed with blindness because mental dullness results in inappropriate responses to visual stimuli. Some symptoms, particularly anorexia, resemble those of hypocortisolism caused by medication overdose. For these reasons, careful re-evaluation, including an ACTH stimulation test, is necessary when suspicious symptoms develop.

Diagnosis of a pituitary tumor requires CT or MRI, and good correlation exists between tumor size and the severity of symptoms. In dogs with marked neurologic symptoms, tumors are frequently greater than 10 mm in height, although tumors with a height of only 0.7 to 0.8 mm may occasionally cause symptoms.[76,77] In addition to tumor size, the development of neurologic symptoms probably is related to the tumor growth rate, the size of the skull cavity, and whether peritumoral inflammation or edema is present. Radiation currently is the only treatment available. Most regimens use cobalt-60 teletherapy or a linear accelerator to administer 3.5 to 4 Gy three times a week for 4 to 6 weeks with the animal under general anesthesia. Complications are uncommon, and only rarely do dogs need to be treated with anti-inflammatory doses of steroids because of initial worsening of signs, which probably is related to

radiation-associated brain edema. Other problems include graying of hair at the entrance sites of the beam, scalp epilation, and otitis externa.

It is difficult to draw a final conclusion from the few reports available on radiation therapy, and the optimal treatment protocol has yet to be established. In our experience, hypophyseal tumors are relatively sensitive to radiation, and dramatic improvement may occur in some dogs with severe neurologic symptoms. Generally, the prognosis and severity of clinical signs are inversely related.[78] Dogs with severe neurologic symptoms and a tumor larger than 20 to 25 mm have a much poorer prognosis than dogs with mild to moderate symptoms and a tumor less than 20 mm. It is important to remember that some dogs improve during radiation therapy, whereas others require weeks for improvement or normalization. Therefore dogs should not be euthanized during or shortly after radiation treatment because of lack of improvement.

In most dogs, radiation has little or no effect or only a transient influence on the secretory nature of the tumor, and additional medical treatment is required. Recurrence of neurologic signs weeks to years later is possible, and in such cases deterioration may be rapid.

We currently recommend CT or MRI for every dog with PDH. For dogs with dexamethasone resistance (per LDDS or HDDS tests), we strongly recommend pituitary imaging. For dogs with tumors greater than 7 mm, we suggest radiation therapy regardless of whether neurologic signs are present.

242.3.1.11.1.1 Adrenal tumors.

Adrenal tumors may invade local tissues and vessels and may metastasize. Traumatic and nontraumatic rupture of the tumor may result in intra-abdominal or retroperitoneal hemorrhage or vena caval thrombosis, causing hindlimb edema.[79–81]

242.3.1.11.2 Pulmonary thromboembolism

Pulmonary thromboembolism is a potentially life-threatening complication of hyperadrenocorticism. However, because no systematic studies exist and a definitive diagnosis is often difficult, its incidence is not known. Dogs with hyperadrenocorticism that undergo surgery (e.g., adrenalectomy) are at increased risk of developing pulmonary thromboembolism. Thromboembolism may occur in other organs, but this is probably rare. It is generally accepted that hyperadrenocorticism leads to a state characterized by hypercoagulation. In humans with Cushing's syndrome, this state is thought to be related to an increase in plasma clotting factors, especially factor VIII and the von Willebrand factor complex, and to an impairment of fibrinolytic capacity.[82] Similar mechanisms are thought to occur in dogs. Recently it was shown that dogs with hyperadrenocorticism had elevated levels of factors II, V, VII, IX, X, and XII and of fibrinogen. Antithrombin was decreased, whereas thrombin-antithrombin complexes were increased.[83] Conditions such as hypertension and obesity may also play a role in the development of pulmonary thromboembolism.

An acute onset of respiratory distress (tachypnea, dyspnea, cyanosis) is characteristic of pulmonary thromboembolism, which may be difficult or impossible to diagnose definitively in veterinary patients. Pulmonary thromboembolism can result in a variety of radiographic patterns; in fact, a recent study found no radiographic abnormalities in 27% of 29 cases.[84] Therefore an animal with severe respiratory distress in which no radiographic changes are seen should be suspected of having pulmonary

thromboembolism. Abnormal radiographic findings include interstitial, alveolar, or mixed patterns; pleural effusion; increased diameter and blunting of pulmonary arteries; and decreased vascularity of affected lung lobes with increased vascularity of unaffected lobes. Echocardiography, including Doppler evaluation, is a helpful diagnostic tool in human medicine but needs further investigation in veterinary medicine. In most dogs, arterial blood gas analysis reveals hypoxemia (partial pressure of oxygen [PO_2] less than 70 mm Hg) and hypocapnia (partial pressure of carbon dioxide [PCO_2] less than 35 mm Hg). However, these are nonspecific findings of inefficient gas exchange and cannot be used alone for diagnosis. A definitive diagnosis may be obtained with pulmonary angiography or ventilation and perfusion scanning with radioisotopes. Because these procedures are either invasive or not widely available, a diagnosis often is made on the basis of clinical signs, radiographic findings, and blood gas analysis results.

Treatment is mainly empirical. In experimental conditions emboli begin to dissolve within hours of formation without treatment, and complete resolution has been documented within days. In naturally occurring disease, however, prothrombic tendencies persist. Therapy consists of general support and administration of oxygen and anticoagulants, such as heparin or warfarin. These drugs have no effect on existing emboli but are used to prevent further clot formation. One of several protocols used for heparin treatment involves an initial dosage of 200 to 300 IU/kg given every 8 hours. The dosage must be modified for each dog to maintain the activated partial thromboplastin time (aPTT) at 1.5 to 2.5 times normal. No information is available on the use of low-molecular-weight heparin. Warfarin is administered initially at a dosage of 0.1 to 0.2 mg/kg given orally every 24 hours. During the first few days, heparin should also be given to combat the initial prothrombic effects of warfarin. The warfarin dosage is then adjusted to achieve an aPTT of 1.5 to 2.5 times normal. 1609 1610

Thrombolytic agents, such as streptokinase, have the potential to dissolve clots. However, their effectiveness in naturally occurring disease has not been critically evaluated, probably because of the expense and the risk of life-threatening hemorrhage.

The prognosis in dogs with pulmonary thromboembolism is guarded to grave. Recovery, if it occurs, usually requires at least 7 to 10 days.

No studies have been done on the success of prophylactic treatment in animals at risk of developing pulmonary thromboembolism. In humans with Cushing's syndrome, it has been shown that thromboembolic complications after surgery can be significantly reduced by anticoagulant prophylaxis.[82] It may be advisable to start low-dose heparin therapy several days prior to surgery in dogs with hyperadrenocorticism and to continue administration for several days afterward.

242.3.1.11.3 Diabetes mellitus

Dogs with hyperadrenocorticism may develop diabetes mellitus because of insulin antagonism by glucocorticoids. Insulin resistance results either directly, because of a reduction in the number or efficacy of glucose transporters, or indirectly, because of an increase in the glucose concentration and resultant free fatty acid concentration. Approximately 30% to 40% of dogs with Cushing's syndrome show mild elevations in the glucose concentration, but only about 10% develop overt diabetes mellitus. Diagnosis of diabetes mellitus in a dog with previously diagnosed Cushing's syndrome usually is straightforward. However, it is much more difficult to diagnose Cushing's syndrome in a dog with established diabetes mellitus. It often is not possible to make a diagnosis based on clinical signs. Both diseases are characterized by polydipsia, polyuria, polyphagia, hepatomegaly, and sometimes weakness. Also, in

dogs with both endocrine diseases, skin and haircoat changes typical of Cushing's syndrome (bilateral symmetric alopecia, skin atrophy) may not occur or may be very mild. It may not be possible to make a diagnosis based on the results of routine laboratory tests, because a stress leukogram and increased hepatic enzyme activities occur in both diseases. The urine specific gravity in most diabetic dogs is greater than 1.025, whereas dogs with both Cushing's syndrome and diabetes mellitus often have hyposthenuria or isosthenuria. Dogs with diabetes mellitus often have false-positive results on screening tests for Cushing's syndrome, therefore the results of these tests must be interpreted carefully. To avoid false-positive results, we recommend that dogs suspected of having Cushing's syndrome and other severe illness should not undergo screening tests. Screening tests should be performed only after good glycemic control has been achieved; however, this is difficult to impossible in dogs with Cushing's syndrome. In such cases, therefore, positive results may be due to poor glycemic control or concurrent hyperadrenocorticism. Further management of such dogs must be considered carefully based on all clinical and laboratory findings.

242.3.1.11.4 Urinary tract infection, pyelonephritis, and calcium-containing uroliths

Nearly 50% of dogs with hyperadrenocorticism have a bacterial urinary tract infection. Dysuria and pyuria may not occur because of the anti-inflammatory and immunosuppressive effects of steroids. Hyperadrenocorticism may also predispose dogs to calcium-containing uroliths, because glucocorticoids increase renal calcium excretion.

242.3.1.11.5 Pancreatitis

Anecdotal reports indicate that hyperadrenocorticism may predispose dogs to pancreatitis. A recent study found that the risk of developing fatal acute pancreatitis was increased by hyperadrenocorticism, as well as by other factors.[85] The mechanism for this is unknown, but it may result from disturbed lipid metabolism.

242.3.1.11.6 Degenerative and immune-mediated diseases

The anti-inflammatory and immunosuppressive effects of cortisol can mask concurrent problems. The most common of these are degenerative arthropathy and skin allergy, which may become apparent once treatment is initiated and cortisol concentrations decrease.

242.3.1.11.7 Hypertension and glomerular disease

Systemic hypertension occurs in a large percentage of dogs with hyperadrenocorticism. Blood pressure can remain elevated despite resolution of hypercortisolemia. According to a recent study, aldosterone does not appear to contribute to hypertension in dogs with hyperadrenocorticism.[86] The major cause of hypertension may be excess cortisol, which enhances sensitivity to endogenous vasoconstrictors.

Hypertension may cause or contribute to glomerular damage and may lead to glomerulosclerosis. Glucocorticoids may also cause glomerulonephritis (see Chapter 261). Both types of glomerular lesions are associated with proteinuria.

242.4 HYPERADRENOCORTICISM IN CATS

Hyperadrenocorticism is an endocrine disorder not commonly recognized in cats. Over a 10-year period, one university clinic diagnosed Cushing's syndrome in more than 800 dogs and in only 34 cats.[26]

Similar to the incidence seen in dogs, 80% to 85% of cats have PDH, and 10% to 15% have an FAT. Adenomas and carcinomas occur with equal frequency. Adrenal tumors may secrete excessive amounts of steroids other than cortisol. Two recent case reports described cats with clinical signs of hyperadrenocorticism caused by a progesterone-secreting adrenal mass.[87,88]

242.4.1 Clinical Findings

Middle-aged to older cats are most commonly affected with hyperadrenocorticism. There does not seem to be a breed predilection; however, approximately 70% of feline cases are female. The most common clinical signs are polydipsia, polyuria, and polyphagia. Most authors have assumed that these symptoms are caused by diabetes mellitus, which develops in approximately 80% of cases, and that they therefore are late signs of hyperadrenocorticism. However, a recent case study described polydipsia and polyuria in two cats with hyperadrenocorticism that did not have concurrent diabetes mellitus and in one cat that had hyperadrenocorticism for 8 months before diabetes mellitus developed.[89] Other frequent findings include pendulous abdomen, generalized muscle wasting, lethargy, and obesity. Many cats have dermatologic symptoms, including hair loss; unkempt haircoat; truncal or patchy alopecia; fragile, thin skin prone to traumatically induced tears (so-called feline fragile skin syndrome); and secondary infections (including demodicosis). Hepatomegaly and weight loss occur less frequently.

Hyperglycemia is the most frequent laboratory abnormality. Only 10% of dogs with hyperadrenocorticism develop overt diabetes mellitus, whereas as many as 80% of cats with Cushing's syndrome are diabetic. Cats seem to be more sensitive to the diabetogenic effects of steroids than dogs, and in many cases it is only after diabetes mellitus has been diagnosed that hyperadrenocorticism is suspected. Insulin resistance is a typical feature of diabetes mellitus caused by hyperadrenocorticism. However, it should be noted that not all cats with Cushing's syndrome and concurrent diabetes mellitus are insulin resistant.

Other findings include hypercholesterolemia and an increase in ALT activity, which may be caused by hyperadrenocorticism or diabetes mellitus. Some cats have elevated ALP activity. Because the activity of a steroid-induced isoenzyme is not increased, this elevation is thought to be associated with diabetes mellitus (and hepatic lipidosis) rather than with hyperadrenocorticism.[90]

1610 1611

242.4.1.1 Specific Endocrine Testing

A diagnosis of hyperadrenocorticism should be based on the results of one or more of the screening tests (urine C:C ratio, ACTH stimulation test, LDDS test). The endogenous ACTH concentration, an HDDS test, and adrenal ultrasonography can be used to differentiate PDH from an FAT in cats.

242.4.1.2 Urine Creatinine to Cortisol Ratio

Slightly more than 70% of cortisol (free cortisol and metabolites) is eliminated in the urine in dogs, whereas only 18% is eliminated in the urine of cats. Despite this difference, the urine C:C ratio of cats with

hyperadrenocorticism is significantly higher than that of healthy cats, and this test can be used in the diagnosis of Cushing's syndrome.[91] Urine should be collected by the owner at home. It is important to remember that false-positive results may be caused by other disease processes. Goosens et al.[91] reported a reference range of 2 to 36 × 10^{-6} based on the results of 42 healthy cats. Our reference range, using 31 healthy cats, was 0 to 4 × 10^{-6}. This discrepancy is possibly due to the different types of radioimmunoassay used. The amount of cortisol metabolites measured varies among assays, therefore it is critical that reference ranges be established for each assay.

242.4.1.3 ACTH Stimulation Test

In both dogs and cats, the ACTH stimulation test is mainly a test of adrenal reserve, and its major role is to rule in or rule out hypoadrenocorticism. The test's sensitivity is low, and because a variety of nonadrenal illnesses can cause abnormal test results, its specificity is also low. According to the test protocol most often used, blood samples for cortisol determination are taken before and 30 and 60 minutes after intramuscular administration of 125 µg/cat of a synthetic polypeptide containing the first 24 aminoacids of ACTH (e.g., Cortrosyn, Synacthen). The time to maximum peak cortisol response is longer and the maximum cortisol concentration is significantly higher after intravenous administration than after intramuscular administration. Therefore the protocol for intravenous administration is to collect blood samples before and 60 and 90 minutes after administration of ACTH. Because peak effect of cortisol is less consistent in the cat than in the dog, two post-ACTH samples are recommended. Reference ranges for the cat are slightly lower than those for the dog and should be established for the laboratory and protocol used. In our laboratory, the upper limit for the normal post-ACTH cortisol concentration using the intramuscular protocol is 13 µg/dL.[92] We consider levels between 13 and 16 µg/dL to be borderline, and a concentration above 16 µg/dL to be consistent with hyperadrenocorticism.

242.4.1.4 Low-Dose Dexamethasone Suppression Test

The degree and duration of adrenocortical suppression after dexamethasone administration is more variable in cats than in dogs. It appears that a dosage of 0.1 mg/kg of dexamethasone suppresses cortisol levels in healthy cats and cats with nonadrenal illness more reliably than 0.01 mg/kg of dexamethasone, which is the dosage used in dogs. Currently, the protocol most often used involves collection of blood samples for production of plasma or serum before and 4 and 8 hours after intravenous administration of 0.1 mg/kg of dexamethasone. Cortisol levels of less than 1 µg/dL at 4 and 8 hours are considered normal, levels between 1 and 1.4 µg/dL are borderline, and levels greater than 1.4 µg/dL are consistent with hyperadrenocorticism. Post-dexamethasone suppression of cortisol concentrations at 4 and 8 hours does not occur in cats with an FAT. Approximately 70% of cats with PDH show no or inadequate suppression.[90]

242.4.1.5 Measurement of Endogenous ACTH

Healthy cats may have very low ACTH concentrations, therefore the measurement of endogenous ACTH test can be used only after a diagnosis of hyperadrenocorticism has been made. Normal to elevated levels of ACTH support a diagnosis of PDH, and low to undetectable levels indicate an FAT. Sample handling is critical (see discussion earlier in this chapter).

242.4.1.6 High-Dose Dexamethasone Suppression Test

Compared with dogs, a higher dose of dexamethasone (1 mg/kg) has been advocated to differentiate between PDH and an FAT in cats; however, very limited information is available. Blood samples should be taken before and 4 and 8 hours after administration of dexamethasone. Suppression (less than 50% of baseline or less than 1.4 μg/dL) is consistent with PDH. No or insufficient suppression may be due either to an FAT or to PDH and cannot be used to differentiate between the two conditions.

242.4.2 Adrenal Ultrasonography

High-resolution transducers have made ultrasonographic visualization of the adrenal glands possible in cats, and reference ranges have been reported.[92] Symmetric adrenal glands of normal or enlarged size are suggestive of PDH, whereas unilateral enlargement or an adrenal gland with a masslike appearance suggests an FAT. Detailed information on the ultrasonographic appearance of the adrenal glands in cats with hyperadrenocorticism currently is limited.

242.4.3 Treatment

Hyperadrenocorticism is a debilitating disease in the cat. The deleterious effects of chronic hypercortisolism on skin fragility as well as on immune and cardiovascular function are frequently responsible for the death of untreated cats. Therefore treatment should be pursued, although compared to dogs, options are more limited and medical treatment is not as successful.

242.4.3.1 Adrenalectomy

Adrenalectomy (unilateral in cats with an FAT, bilateral in cats with PDH or bilateral FATs) appears to be the most successful of the treatment options available.[93] The surgical protocol and the medical management of cats during and after the procedure are similar to those followed in dogs. After discontinuation of intravenous steroids, oral prednisolone (2.5 mg twice daily) should be given. Mineralocorticoids (fludrocortisone, 0.1–0.2 mg/cat) should be administered to cats after bilateral adrenalectomy or to those that have hyperkalemia and/or hyponatremia after surgery. Serum electrolyte concentrations should be evaluated twice daily for several days after surgery. After bilateral adrenalectomy, cats require lifelong supplementation with both mineralocorticoids and glucocorticoids, whereas after unilateral adrenalectomy, supplementation generally can be weaned off over a 2-month period. Postsurgical complications are common and include sepsis, pancreatitis, thromboembolism, and hypoadrenocorticism. Surgery-related death occurs in about 30% to 40% of cases.

Successful adrenalectomy typically results in resolution or marked improvement of clinical signs within 2 to 4 months. In about 50% of cases, diabetes resolves, and in others the insulin requirement decreases.[89,93]

242.4.3.2 Hypophysectomy

Recently, transsphenoidal hypophysectomy for the treatment of PDH was described in seven cats.[94] Two cats died within 4 weeks of surgery. Remission was achieved in five cats, although relapse occurred in one of these 19 months after surgery. Diabetes mellitus resolved in two of the four cats that had the disease. In

1611

1612

the future, transsphenoidal hypophysectomy may be the treatment of choice for cats with hyperadrenocorticism.

242.4.3.3 Radiation Treatment

The success rate for radiation treatment in cats has been variable at best. However, the number of cats treated with radiation is very small, therefore conclusions are difficult to draw.

242.4.3.4 Medical Treatment

A number of different medical protocols have been used in cats with hyperadrenocorticism. However, success rates are variable or poor, and long-term results are often disappointing. Medical treatment may be indicated for the presurgical management of hyperadrenocorticism and may improve the outcome of surgery.

242.4.3.4.1 Mitotane

The use of mitotane to treat hyperadrenocorticism has been discouraged in the past because of a perceived sensitivity of cats to chlorinated hydrocarbons. In addition, the success rate of mitotane treatment was reported to be poor.[26] One recent report describes successful long-term mitotane treatment in a cat with PDH.[95]

242.4.3.4.2 Ketoconazole

Treatment with ketoconazole (15 mg/kg given twice a day) resulted in clinical improvement in some cats and no response in others. Severe thrombocytopenia was reported in one cat and was thought to be due to an adverse drug reaction.

242.4.3.4.3 Metyrapone

Metyrapone has been successfully used as a treatment prior to bilateral adrenalectomy.[96,97] The optimal dose was 65 mg/kg given orally every 12 hours.

242.4.3.4.4 Trilostane

There are no published reports on the use of trilostane in cats with hyperadrenocorticism.

242.4.3.5 Prognosis

Hyperadrenocorticism in cats is a serious disease with a guarded to grave prognosis. Medical therapy has limited success, and the outcome of surgery is often hampered by the debilitated condition of the patient.

242.4.4 Hyperaldosteronism

Primary hyperaldosteronism, also called *Conn's syndrome* in human medicine, is a very rare disease in dogs and cats. It is usually caused by a unilateral adenoma or rarely by a carcinoma of the zona glomerulosa of the

adrenal gland. Bilateral adrenal hyperplasia in association with hyperaldosteronism has been reported in only one dog.[98] Aldosterone is the principal regulator of sodium and potassium balance and is important in the maintenance of normal intravascular fluid volume. It also plays a role in the control of acid-base equilibrium. In conditions involving excessive autonomous aldosterone secretion, sodium and water are retained, leading to expansion of the extracellular fluid volume and hypertension. The increase in sodium and water is usually limited by an "escape" mechanism. Nevertheless, hyperaldosteronism tends to be associated with extracellular volume expansion and arterial hypertension. The renin system is suppressed. Increased potassium excretion leads to progressive depletion of body potassium, development of hypokalemia, and hypokalemic metabolic alkalosis. Aldosterone also stimulates the excretion of phosphorus and magnesium. Other characteristics of hyperaldosteronism include resistance to vasopressin and disturbed vasopressin release.[99]

Clinical signs consist of weakness, which may be episodic; ventroflexion of the neck (in cats); stiff gait; myalgia; and lethargy. Hypertension may be present and may cause hypertensive retinopathy. Recently polydipsia and polyuria were described as the lead symptoms in a dog with an aldosteronoma.[99] Moderate to severe hypokalemia is the typical and most consistent finding. The sodium concentration may be normal or only slightly elevated. Definitive diagnosis requires demonstration of an inappropriately elevated aldosterone concentration with a low plasma renin concentration. Ultrasonography and CT are useful for localization and staging of the tumor. Initial treatment should be directed at alleviation of hypokalemia. Surgical intervention is the treatment of choice for tumors with no detectable metastases. For animals with metastases or in the rare case of bilateral hyperplasia, potassium supplementation and spironolactone, an aldosterone antagonist, can be given.

243 CHAPTER • 243 Hypoadrenocorticism

Michael E. Herrtage

Hypoadrenocorticism is a syndrome that results from deficient production and secretion of glucocorticoids and/or mineralocorticoids by the adrenal cortices. Destruction of more than 90% of both adrenal cortices causes a deficiency of all adrenocortical hormones and the resulting clinical condition is termed *primary hypoadrenocorticism* (Addison's disease). Secondary hypoadrenocorticism is characterized by deficient production and secretion of adrenocorticotropic hormone, ACTH, which leads to atrophy of the adrenal cortices and impaired secretion of glucocorticoids. The production of mineralocorticoids, however, usually remains adequate because ACTH has only minor tropic effects on mineralocorticoid production. Primary and secondary hypoadrenocorticism differ not only in their pathophysiology but also in their clinical presentations.

243.1 ANATOMY AND PHYSIOLOGY

One adrenal gland is located craniomedial to each kidney, in retroperitoneal fat. The right adrenal gland lies between the medial surface of the cranial pole of the right kidney and the lateral aspect of the caudal vena cava at the level of the thirteenth thoracic vertebra. The right phrenicoabdominal vein crosses the ventral surface of the gland before joining the caudal vena cava. The left adrenal gland is found craniomedial to the border of the left kidney at the level of the second lumbar vertebra. Medially it is bounded by the descending aorta between the cranial mesenteric artery and the left renal artery.

Together, both adrenal glands from normal dogs weigh about 1 g. On cross-section, the adrenal cortex appears pale yellow whereas the medulla is dark brown. The cortex completely surrounds the medulla and consists of three distinct zones: the outer zona glomerulosa (arcuata) makes up about 25% of the cortex, the middle zona fasciculata makes up approximately 60%, and the inner zona reticularis accounts for the remaining 15% of the cortex. The medulla is adjacent to the zona reticularis, which makes up 10% to 20% of the total volume of the adrenal gland.

The adrenal cortex produces about 30 different hormones, many of which are believed to have little or no clinical significance (Figure 243-1). The hormones can be divided into three groups based on their predominant actions: *mineralocorticoids,* which are important in electrolyte and water homeostasis; *glucocorticoids*, which promote gluconeogenesis; and small quantities of sex hormones, particularly male hormones that have weak androgenic activity.

Aldosterone is the most important mineralocorticoid and is produced by the zona glomerulosa. The principal glucocorticoid, cortisol, and the sex hormones are produced in the zonas fasciculata and reticularis. Glucocorticoid and mineralocorticoid release are controlled by separate mechanisms (Figure 243-2).

243.1.1 Regulation of Glucocorticoid Release

Glucocorticoid release is controlled almost entirely by adrenocorticotrophic hormone (ACTH) secreted by the anterior pituitary, which in turn, is regulated by corticotrophin releasing hormone (CRH) from the hypothalamus (see Figure 243-2). CRH is secreted by the neurons in the anterior portion of the paraventricular nuclei within the hypothalamus and is transported to the anterior pituitary by the portal circulation, where it stimulates ACTH release. There is probably an internal or “short loop” negative feedback control by ACTH on CRH. ACTH secreted into the systemic circulation causes cortisol release with concentrations rising almost

immediately. Cortisol has direct negative feedback effects on (1) the hypothalamus to decrease formation of CRH and (2) the anterior pituitary gland to decrease the formation of ACTH. These feedback mechanisms help regulate the plasma concentration of cortisol.

243.1.2 Regulation of Mineralocorticoid Release

Aldosterone release is influenced primarily by the reninangiotensin system and by plasma potassium levels (see Figure 243-2). Renin is secreted into the blood by the cells of the juxtaglomerular apparatus within the kidneys. This apparatus consists of specialized cells in the wall of the afferent arteriole immediately proximal to the glomerulus as well as specialized epithelial cells of the distal convoluted tubule adjacent to that arteriole, the macula densa. Renin release may be stimulated by stretch receptors in the juxtaglomerular apparatus in response to hypotension, reduced renal blood flow, or by sodium and chloride receptors in the macula densa. Renin is also released by sympathetic nerve stimulation and is inhibited by angiotensin II, antidiuretic hormone, hypertension, and increased reabsorption of sodium by the renal tubules.

Renin is a proteolytic enzyme that splits circulating angiotensinogen, an alpha-2 globulin produced by the liver, into the decapeptide, angiotensin I. Angiotensin I is hydrolysed to the octapeptide, angiotensin II by angiotensin converting enzyme found almost exclusively in the pulmonary capillary endothelium. Angiotensin II is a powerful vasoconstrictor that also stimulates aldosterone secretion from the zona glomerulosa. Through its action on the distal convoluted tubule, aldosterone has negative feedback effects on the juxtaglomerular apparatus. Potassium has a direct stimulatory effect on the zona glomerulosa cells to release aldosterone. ACTH and sodium play less significant roles in aldosterone secretion. ACTH is necessary to maintain normal aldosterone output. In the absence of ACTH, the zona glomerulosa partially atrophies, causing mild to moderate aldosterone deficiency compared with almost total atrophy of the other zones.

The main function of aldosterone is to protect against hypotension and potassium intoxication. Aldosterone promotes sodium, chloride, and water reabsorption as well as potassium excretion in many epithelial tissues including the intestinal mucosa, salivary glands, sweat glands, and kidneys. Its main site of action is the renal tubule, where it promotes sodium and chloride reabsorption in the proximal convoluted tubule and sodium reabsorption by exchange with potassium in the distal convoluted tubule. It is one of the complex regulatory systems for the regulation of extracellular fluid electrolyte concentrations, extracellular fluid volume, blood volume, and arterial pressure.

243.2 PRIMARY HYPOADRENOCORTICISM (ADDISON'S DISEASE)

Primary hypoadrenocorticism results from progressive destruction of the adrenal cortices, which must involve more than 90% of the function before clinical signs become apparent. The condition is also referred to as Addison's disease, after the English physician, Thomas Addison, who in 1855 described the syndrome in humans. In those days, the most common cause was destruction of the adrenals by chronic tuberculosis.

Primary hypoadrenocorticism is rare in the dog although probably occurs more frequently than is recognized. Hypoadrenocorticism appears to be rare in cats with only one case series and a few case reports published.[1–3] The clinical signs, diagnosis, and treatment of hypoadrenocorticism are similar in the dog and cat.

243.3 PATHOGENESIS

243.3.1 Idiopathic Adrenocortical Atrophy

This is the most common cause in the dog and is thought to be the end result of immune-mediated destruction of the adrenal cortices. Immune-mediated destruction of the adrenal cortices is the most common cause of human primary hypoadrenocorticism and 21-hydroxylase (see Figure 243-1) is considered to be the major autoantigen.[4] The presence of antiadrenal antibodies in two dogs and characteristic histopathologic findings in another support the hypothesis of immune-mediated destruction.[5] The increased predisposition of primary hypoadrenocorticism in young to middle-aged female dogs is also suggestive of an immune-mediated disease. An immune-mediated etiology is also suspected in the cat.

In approximately 50% to 60% of humans with primary hypoadrenocorticism, the disease is associated with other immune-mediated disorders such as Hashimoto's thyroiditis, insulin-dependent diabetes mellitus, hypoparathyroidism, primary gonadal failure, and atrophic gastritis. Autoimmune polyglandular disease has also been recognized in the dog with hypoadrenocorticism and hypothyroidism being the most common combination, but diabetes mellitus and/or hypoparathyroidism may also occur concurrently.[6]

1613

1615

Figure 243-1 Major biosynthetic pathways of adrenocortical steroid production. The zona glomerulosa produces mineralocorticoids. The zona fasciculata and reticularis produce glucocorticoids and sex hormones.

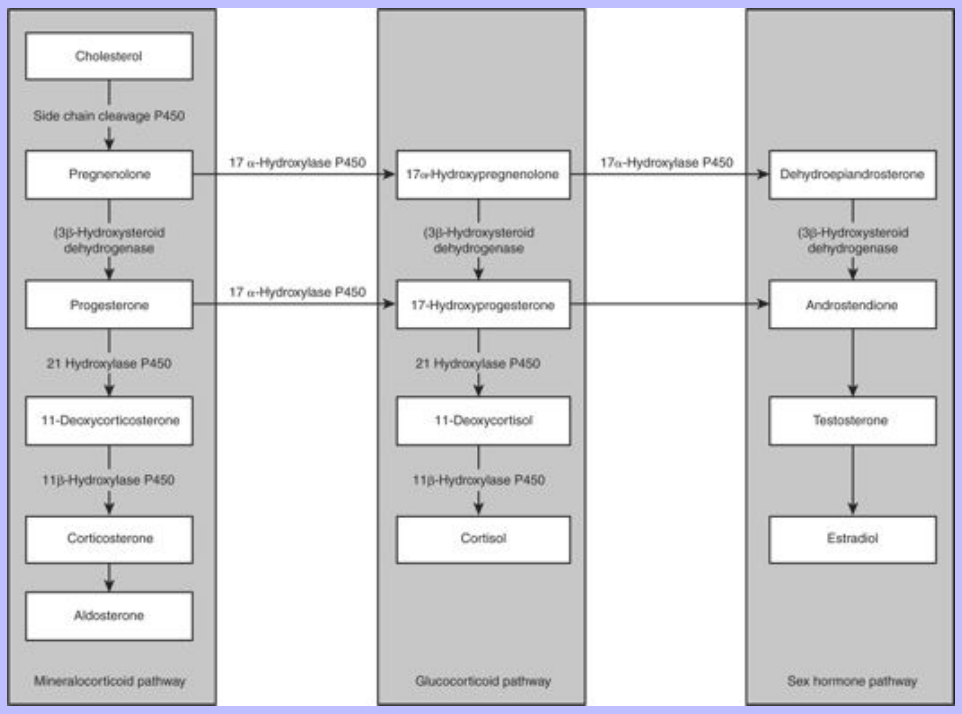

Figure 243-2 Regulation of glucocorticoid and mineralocorticoid release. Corticotrophin releasing hormone (CRH), adrenocorticotrophic hormone (ACTH)

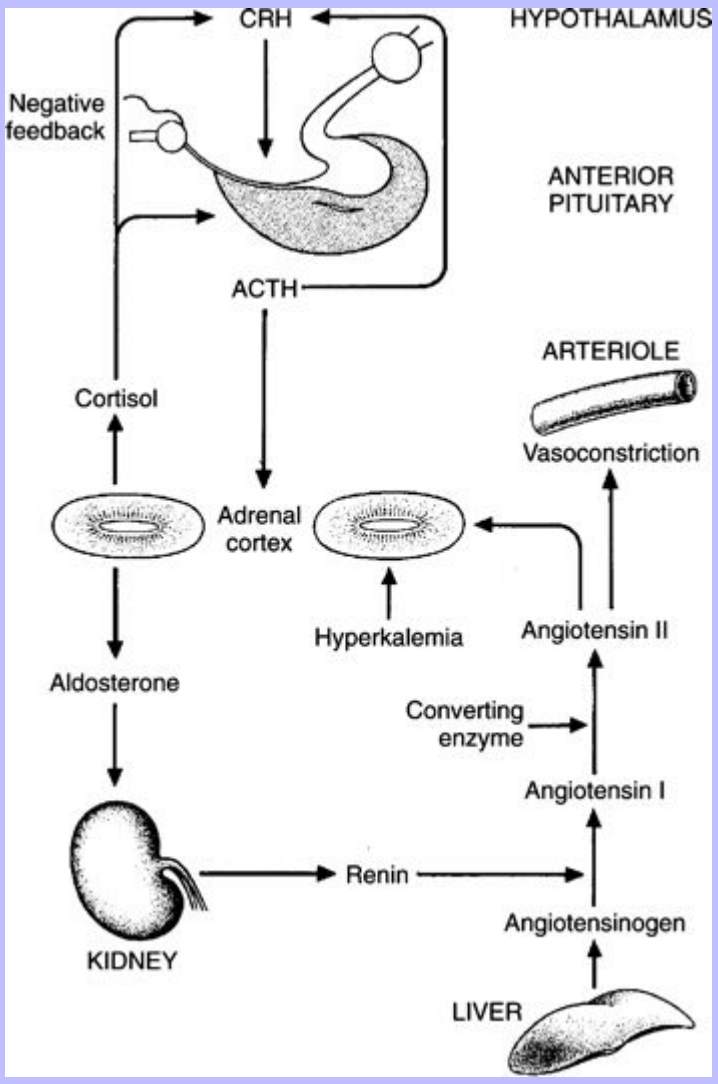

243.3.2 Drug-Induced Adrenocortical Necrosis

Iatrogenic hypoadrenocorticism is a possible complication of mitotane therapy used in the treatment of canine hyperadrenocorticism (see Chapter 242). Although mitotane usually spares the zona glomerulosa and therefore mineralocorticoid secretion, cases of complete adrenocortical failure may occur in as many as 5% of treated dogs. In most of these dogs, the adrenal cortex does not recover when mitotane therapy is withdrawn and permanent mineralocorticoid and glucocorticoid replacement therapy is required. This is a separate entity from

transient glucocorticoid deficiency, which may occur following overdosage of mitotane during the induction or maintenance phase of therapy for hyperadrenocorticism.

Adrenocortical necrosis has also been reported following treatment of canine hyperadrenocorticism with trilostane.[7] Since trilostane is a reversible inhibitor the 3β-hydroxysteroid dehydrogenase enzyme system, which blocks adrenal synthesis of glucocorticoids, mineralocorticoids, and sex hormones (see Figure 243-1), this complication is not common. However, awareness of this possible complication is important because prompt treatment is required to correct this life-threatening situation.

243.3.3 Bilateral Adrenalectomy

The surgical removal of both adrenals has been used for the treatment of canine and feline pituitary-dependent hyperadrenocorticism. The surgery is technically difficult and there is a high morbidity and mortality rate even when performed by experienced surgeons. These dogs and cats must be treated for hypoadrenocorticism with replacement hormone therapy for the rest of their lives.

243.3.4 Other Possible Causes

Rarely, canine hypoadrenocorticism can be caused by hemorrhage or infarction of the adrenal glands, granulomatous or neoplastic involvement of the adrenal glands, amyloidosis of adrenal cortices, or following trauma to the adrenal glands.

243.4 PATHOPHYSIOLOGY

Adrenocortical pathology leads to mineralocorticoid and glucocorticoid deficiency. Aldosterone is the major mineralocorticoid and promotes sodium, chloride, and water reabsorption as well as potassium excretion in many epithelial tissues, including the intestinal mucosa, salivary glands, sweat glands, and kidneys. Its main site of action is the renal tubule, where it promotes sodium and chloride reabsorption in the proximal convoluted tubule and sodium reabsorption by exchange with potassium in the distal convoluted tubule. Deficiency of aldosterone causes impaired ability to conserve sodium and water and failure to excrete potassium leading to hyponatremia and hyperkalemia. Hyponatremia induces lethargy, depression, and nausea while causing development of hypovolemia, hypotension, reduced cardiac output, and decreased renal perfusion. Hyperkalemia causes muscle weakness, hyporeflexia, and impaired cardiac conduction. Glucocorticoid deficiency causes decreased tolerance of stress, loss of appetite, vomiting, diarrhea, abdominal pain, and lethargy.

243.5 SIGNALMENT

243.5.1 Breed

Many breeds of dog have been reported with hypoadrenocorticism, but great Danes, Portuguese water dogs, Rottweilers, standard Poodles, West Highland white terriers, and soft-coated Wheaten terriers appear to be at greater risk of developing hypoadrenocorticism compared with dogs of other breeds.[8] Evidence of familial occurrence and the possibility of an hereditary factor has been suggested in standard Poodles,[9,10] bearded collies,[11,12] and Leonbergers,[13] although the precise genetic mechanism responsible for inheritance of the disease remains undetermined.

No breed predisposition has been identified in the cat. Most reported cases of hypoadrenocorticism have been in domestic shorthaired and longhaired cats.

243.5.2 Age

Hypoadrenocorticism appears to be a disease of the young and middle-aged dog with an age range of 2 months to 14 years and a median age of 4 to 6 years. A similar age range has been noted in cats with hypoadrenocorticism.

243.5.3 Sex

Approximately 70% of dogs with naturally occurring hypoadrenocorticism are female and sexually intact females have been shown to have a significantly higher risk of developing hypoadrenocorticism than spayed females.[8] This is similar to autoimmune Addison's disease in humans and supports the hypothesis of an immune-mediated pathogenesis in most dogs. However, in the bearded collie and standard poodle, in which hypoadrenocorticism is considered to be highly heritable, both sexes are affected with equal probability.[10,12] No sex prediposition has been reported in cats.

1615 1616

243.6 CLINICAL SIGNS

The clinical signs of primary hypoadrenocorticism vary from mild to severe with the progression being either acute or chronic. The chronic form of hypoadrenocorticism with clinical signs present for weeks to months is more common than the acute disease in the dog, although the distinction between these two syndromes is not always clear.

243.6.1 Acute Primary Hypoadrenocorticism

The clinical appearance of acute hypoadrenocorticism is that of hypovolemic shock (an Addisonian crisis). The animal is usually found in a state of collapse or collapses when stressed. Other signs include weak pulse, profound bradycardia, abdominal pain, vomiting, diarrhea, dehydration, and hypothermia. Bradycardia is an inappropriate response in a collapsed, hypovolemic patient and warrants immediate investigation. Acute hypoadrenocorticism is rapidly progressive, life threatening, and represents a true medical emergency. Symptomatic therapy with aggressive fluid therapy will help most afflicted dogs and cats by allowing more time to make a diagnosis.

243.6.2 Chronic Primary Hypoadrenocorticism

The clinical signs in the chronic form are often vague and nonspecific and may be exacerbated by stress (Box 243-1). The diagnosis should be considered in any dog or cat with a waxing and waning type of illness or that shows episodic weakness and collapse. The most consistent clinical signs include anorexia, vomiting, lethargy, weight loss, diarrhea, obtundation, depression, shaking or shivering, muscle fasciculations, severe muscle weakness, and polydipsia/polyuria. Less common signs such as regurgitation due to megaesophagus[14], painful muscle cramping[15], and hypoglycemic seizures[16] have been reported. The severity of each sign can vary during the course of the disease and may be interspersed with periods of apparent good health often following nonspecific veterinary therapy, usually consisting of cage rest, glucocorticoid therapy and/or parenteral fluid

administration. Hypoadrenocorticism can easily be mistaken for primary renal, gastrointestinal, or neuromuscular diseases.

Common findings on physical examination apart from obtundation and weakness include dehydration, bradycardia, weak femoral pulses, and prolonged capillary refill time. In a few cases, severe gastrointestinal hemorrhage with melena, hematochezia, and occasionally hematemesis can occur, resulting in profound anemia.[17] Since the history and clinical findings are not pathognomonic for hypoadrenocorticism, a high index of suspicion and a careful and critical evaluation of dogs and cats are necessary to arrive at the correct diagnosis.

243.7 CLINICOPATHOLOGIC FINDINGS

243.7.1 Hematology

Hematologic changes may include lymphocytosis, eosinophilia and mild normocytic, normochromic, nonregenerative anemia (Box 243-2). However, these findings are not as consistent as those changes seen in hyperadrenocorticism. Normal or increased eosinophil and lymphocyte counts in a sick animal with signs compatible with hypoadrenocorticism are significant, because the expected response to stress would result in eosinopenia and lymphopenia. A mild anemia may not be appreciated until the dog has been rehydrated because of the hemoconcentration effect of dehydration. Profound anemia (PCV<20%) is usually found in association with gastrointestinal hemorrhage.

243.7.1.1 Box • 243-1 Clinical Signs of Primary Hypoadrenocorticism (Addison's Disease)

Anorexia

Lethargy/depression

Weakness, usually episodic

Vomiting

Waxing and waning illness

Weight loss or failure to gain weight

Dehydration

Diarrhea or occasionally constipation

Polydipsia and/or polyuria

Collapse or syncope

Restlessness/shaking/shivering

Regurgitation

Painful muscle cramps

Melena

Weak pulse

Bradycardia

Abdominal pain

243.7.2 Biochemistry

The most consistent laboratory findings in hypoadrenocorticism are prerenal azotemia, hyponatremia, hyperkalemia, and mild to moderate metabolic acidosis. However, approximately 10% of dogs with primary hypoadrenocorticism have normal serum electrolyte concentrations and these cases are referred to as *atypical Addison's disease*.[18]

243.7.2.1 Blood Urea, Creatinine, and Urine Specific Gravity

Blood urea nitrogen (BUN) and serum creatinine concentrations are increased secondary to reduced renal perfusion and decreased glomerular filtration rate. Reduced renal perfusion results from hypovolemia, reduced cardiac output and hypotension, which in turn result from chronic fluid loss through the kidneys, acute fluid loss through vomiting, and/or diarrhea and inadequate fluid intake. This prerenal azotemia is often associated with hyperphosphatemia. Increases in BUN also result from gastrointestinal hemorrhage, which is common. This usually explains the discordant moderate-to-severe increase in BUN in a dog or cat with Addison's disease that has only a mild-to-moderate increase in serum creatinine concentration.

Prerenal azotemia is usually associated with concentrated urine (specific gravity >1.030) whereas the urine concentration in dogs and cats with primary renal failure is often isothenuric or only mildly concentrated (1.008 to 1.025). The urine specific gravity in dogs and cats with hypoadrenocorticism is variable but is usually between 1.015 and 1.030, which may cause confusion for the clinician as it is more dilute than would be expected in an animal with prerenal azotemia. This reduction in urine specific gravity develops in hypoadrenocorticism because of impaired concentrating ability secondary to chronic sodium loss reducing the renal medullary concentration gradient.[19] With appropriate fluid therapy, the blood urea and creatinine

concentrations in cases of hypoadrenocorticism will usually quickly return to normal confirming that the azotemia is prerenal.

243.7.2.1.1.3

Urinalysis

Specific gravity variable (usually 1.015 to 1.030)

243.7.2.2 Sodium and Potassium Concentrations

The serum sodium concentration is usually less than 135 mEq/L and the serum potassium concentration usually greater than 5.5 mEq/L. However, because of the variability of these two abnormalities, the ratio of sodium to potassium may be more reliable than the absolute values. The normal ratio varies between 27:1 and 40:1, whereas in dogs and cats with hypoadrenocorticism, the ratio is usually less than 25:1 and may be below 20:1. Serum chloride concentration is also reduced in association with sodium and frequently chloride concentrations below 100 mEq/L are found in animals with hypoadrenocorticism.

Concurrent hypovolemia, hyponatremia, and hyperkalemia may develop in other conditions apart from hypoadrenocorticism such as gastrointestinal disease, chronic blood loss, acute and chronic renal failure, chronic hepatic failure, chronic heart failure, repeated drainage of chylous and non-chylous pleural effusions, lymphangiosarcoma, and pregnancy (Box 243-3).[20–22] In a recent review of low sodium: potassium ratios in 34 dogs, renal failure or urinary tract disease leading to decreased urine excretion of potassium accounted for the low ratio in most of the dogs with sodium: potassium ratios of between 19.9 and 15.[23] These low ratios were more strongly associated with high serum potassium concentrations than with low serum sodium concentrations. Four of the dogs in that study had sodium: potassium concentrations ratios of less than 15 and each dog had hypoadrenocorticism. However, although *suggestive* of hypoadrenocorticism, a low sodium: potassium ratio of less than 15 is not *diagnostic* of hypoadrenocorticism. Pseudohyperkalemia, which is defined as a spurious increase in serum or plasma potassium concentration caused by in vitro changes, may be seen in hemolysed blood samples, especially from Akitas[24] and in dogs with thrombocytosis or extreme leucocytosis.[25]

243.7.2.2.1 Box • 243-3 Differential Diagnosis for Significant Hyperkalemia and/or Hyponatremia in Dogs and Cats

Renal or urinary tract disease

- Acute primary renal failure
- Chronic severe oliguric or anuric renal failure (rare)
- Urethral obstruction
- Uroabdomen (ruptured ureter, bladder, or urethra)
- Postobstructive diuresis
- Nephrotic syndrome

Hypoadrenocorticism

- Severe gastrointestinal disease
  - Parasitic infestations
    - Trichuriasis
    - Ascariasis
    - Ancylostomiasis
  - Salmonellosis
  - Viral enteritis
    - Parvovirus
    - Distemper
  - Gastric dilatation/volvulus
  - Gastrointestinal perforation
  - Severe malabsorption
  - Idiopathic hemorrhagic enteritis
  - Pancreatitic disease
- Severe hepatic failure
  - Cirrhosis
  - Neoplasia
- Severe metabolic or respiratory acidosis

Congestive heart failure

Massive release of potassium to the extracellular fluid

- Crush injuries
- Aortic thrombosis
- Rhabdomyolysis
  - Heat stroke
  - Exertional
- Massive infections
- Massive hemolysis (rare)

Chylous and non-chylous pleural effusions

Pregnancy

Lymphangiosarcoma

Pseudohyperkalemia

- Japanese Akitas and related breeds
- Severe leukocytosis (>100,000/mm^3)
- Severe thrombocytosis (>1,000,000/mm^3)

Diabetes mellitus

Primary polydipsia

Inappropriate ADH secretion

Drug-induced

Potassium-sparing diuretics

Nonsteroidal anti-inflammatory agents

Angiotensin-converting enzyme inhibitors

Potassium-containing fluids

Most of these diagnosis/conditions are rarely associated with abnormal electrolyte abnormalities.

References 20 through 25.

1617

1618

Approximately 10% of dogs with primary hypoadrenocorticism have normal serum electrolyte concentrations at the time of initial examination. It is generally believed that these dogs with atypical Addison's disease have early or mild primary hypoadrenocorticism and that typical electrolyte abnormalities would develop with time. Rarely isolated primary hypocortisolemia has been reported in dogs that never develop serum electrolyte abnormalities.[26]

243.7.2.3 Calcium Concentration

Mild to moderate hypercalcemia is seen in about a third of dogs with hypoadrenocorticism. Usually these dogs are most severely affected by the disease. The mechanism by which hypercalcemia occurs in hypoadrenocorticism remains to be elucidated, but hemoconcentration, increased renal tubular reabsorption, and decreased glomerular filtration are thought to contribute. The differential diagnosis of hypercalcemia includes neoplasia, primary hyperparathyroidism, chronic renal failure, hypervitaminosis D, and granulomatous disease. In a study of 40 dogs with hypercalcemia, hypoadrenocorticism was the second most common cause and accounted for 25%.[27] In the same study, the degree of hypercalcemia was found to be significantly lower in dogs with hypoadrenocorticism (mean plasma calcium concentration 14.0 ± 1.6 mg/dL) than in lymphoproliferative disease (mean plasma calcium concentration 17.2 ± 2.8 mg/dL).

243.7.2.4 Blood Glucose Concentration

Theoretically, dogs with hypoadrenocorticism should have a tendency to develop hypoglycemia because glucocorticoid deficiency reduces glucose production by the liver and peripheral cell receptors become more sensitive to insulin. However, hypoglycemia is uncommon.[28] The potential for this complication should remain a concern for the clinician as rarely the severity of the hypoglycaemia may result in clinical signs of ataxia, disorientation, or seizures.[16]

243.7.2.5 Serum Albumin Concentration

Moderate to severe hypoalbuminemia has been noted in dogs with hypoadrenocorticism. The pathogenesis of hypoalbuminemia in primary hypoadrenocorticism is unknown, but gastrointestinal hemorrhage, impaired intestinal absorption of nutrients, and impaired albumin synthesis may be involved. The major causes of hypoalbuminemia include increased loss (for example, protein losing nephropathy or enteropathy, blood loss, severe exudation, or hemorrhage into body cavities) and decreased production (for example, severe malabsorption, maldigestion, or malnutrition or inadequate production in chronic liver disease). In one study, 39% of dogs with hypoadrenocorticism were found to have hypoalbuminemia.[29] However, other studies have shown the frequency of hypoalbuminemia to be considerably lower, between 6% and 12% of cases.[8,30] Some of the hypoalbuminomic dogs also have hypocholesterolemia, microhepatica, and/or ascites.

243.7.2.6 Liver Enzyme Concentrations

Mild to moderate increases in liver enzyme activities, such as alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase, are found in some dogs with hypoadrenocorticism. Although the precise cause of these increases is unknown, reduced cardiac output and poor tissue perfusion probably play a role. Increased liver enzyme activities hypoalbuminemia, and hypoglycemia would raise the suspicion of primary hepatic disease in some dogs with hypoadrenocorticism and clinicians should be aware of this potential confusion.

243.7.2.7 Acid-Base Balance

Mild to moderate metabolic acidosis is common in dogs with hypoadrenocorticism. Total carbon dioxide concentrations and serum bicarbonate determinations are reduced. Acidosis develops because reduced aldosterone concentrations impair renal tubular secretion of hydrogen ions. Hypotension and poor renal perfusion are likely to contribute to the acidosis.

243.7.3 Electrocardiographic Findings

Hyperkalemia impairs cardiac conduction and may cause life-threatening arrhythmias. These changes can be assessed by electrocardiography (ECG) (Figure 243-3). Although the ECG changes do not correlate precisely with serum potassium concentrations, probably because of the influence of other electrolyte abnormalities particularly the cardioprotective effects of increased calcium, metabolic acidosis, and impaired tissue perfusion, the following guidelines have proved helpful:

>5.5 mEq/L	peaking of the T wave shortening of the Q-T interval
>6.5 mEq/L	increased QRS duration
>7.0 mEq/L	P wave amplitude decreased
	P-R interval prolonged
>8.5 mEq/L	P wave absent (sinoatrial standstill) severe bradycardia

In some cases, bizarre QRS complexes representing ventricular extrasystoles, paroxysmal ventricular tachycardia, or ventricular fibrillation may be seen and these are most likely the result of hypoxia and/or hyperkalemia.

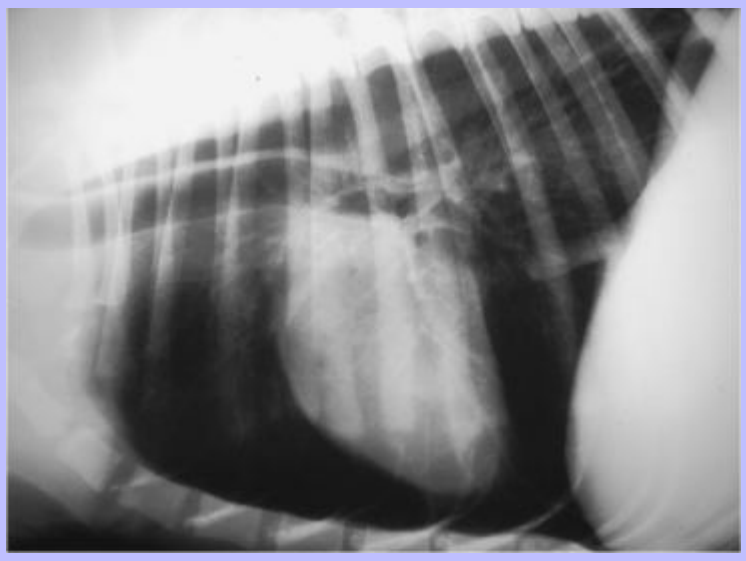
Electrocardiography can also be used for monitoring the response to treatment. An improvement in the ECG tracing suggests a reduction in serum potassium concentration.

243.7.4 Radiographic Findings

Dogs with hypoadrenocorticism may show radiographic signs of hypovolemia, which include: microcardia, decreased size of pulmonary vessels, reduced size of the caudal vena cava, and microhepatica (Figure 243-4). These changes, however, are not specific and only represent hypovolemia and dehydration regardless of the cause. The severity of these radiographic findings usually correlates with the degree of hypovolemia. 1618 1619

Figure 243-3 Electrocardiograms from a 4-year-old bearded collie dog with primary hypoadrenocorticism taken **(A)** before and **(B)** after supplementation with glucocorticoids and mineralocorticoids. Paper speed is 25 mm/sec and sensitivity is 1 cm = 1mV. **A,** The P waves are absent, the T waves are peaked, and there is profound bradycardia. The serum sodium concentration was 138 mEq/L and the serum potassium 9.5 mEq/L. **B,** ECG after treatment showing sinus arrhythmia. The serum sodium concentration was 142 mEq/L and the serum potassium 5.4 mEq/L.

Figure 243-4 Lateral thoracic radiograph of a standard poodle with primary hypoadrenocorticism showing the effects of hypovolemia, including microcardia, decreased pulmonary vasculature, and reduced caudal vena cava. The esophagus is dilated with air in the cranial thorax as evidenced by a dorsal tracheal stripe sign.



A few dogs with hypoadrenocorticism develop esophageal dilation or megaesophagus as a result of generalized muscle weakness and this can be seen on thoracic radiographs as an air-filled, dilated esophagus. Image-intensified fluoroscopy, using barium paste or barium mixed with food demonstrates a complete absence of esophageal peristaltic activity. The cause of esophageal dilatation in hypoadrenocorticism remains unclear but was considered to be attributable to the effect of abnormal sodium and potassium concentrations on membrane potential and neuromuscular function.[31] However, in some dogs with hypoadrenocorticism and megaesophagus, abnormal serum electrolyte concentrations were never documented, which suggests that the esophageal dilatation was associated with glucocorticoid deficiency.[14,32] The megaesophagus resolves rapidly with appropriate treatment for hypoadrenocorticism.

243.7.5 Ultrasonography

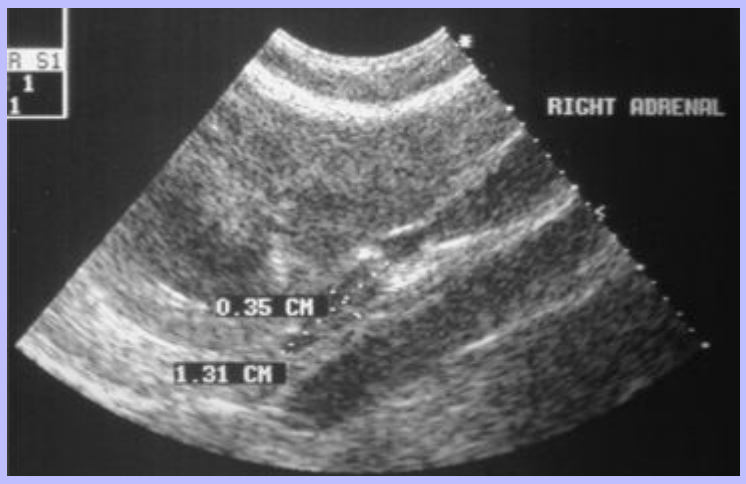
With high resolution ultrasound equipment, it is possible for an experienced ultrasonographer to image the adrenal glands of most normal and diseased dogs. Ultrasonographic examination of the adrenal glands has been performed in dogs with hypoadrenocorticism, and the adrenal glands were shown to be shorter (median values: left adrenal 12.1 mm; right adrenal 13.1 mm) and thinner (median values: left adrenal 2.4 mm; right adrenal 2.5 mm) than those of healthy dogs.[33] However, there is considerable variation in the normal measurements of canine adrenal glands with maximum dimensions (length × thickness) in the range 10 to 52 mm × 2 to 12 mm.[34,35] There is poor correlation between these dimensions and body weight and there are no published normal adrenal measurements for different breeds of dog. Although ultrasonography could not

distinguish between primary and secondary hypoadrenocorticism, the technique was considered to be a useful screening test especially in critically ill animals with acute disease (Figure 243-5).

243.7.6 Blood Pressure

Hypotension is present in nearly all humans with primary hypoadrenocorticism but is an uncommon finding in those with secondary hypoadrenocorticism. No large series of blood pressure measurements in dogs with hypoadrenocorticism have been published, but hypotension has been recorded in individual cases.[36]

Figure 243-5 A longitudinal sonogram of the right adrenal gland of a Labrador retriever with primary hypoadrenocorticism. The adrenal thickness (3.5 mm) and the adrenal length (13.1 mm) have been measured.



243.7.7 Endocrine Tests

243.7.7.1 ACTH Stimulation Test

The ACTH stimulation test is the gold standard test for providing a definitive diagnosis of hypoadrenocorticism. Intravenous synthetic preparations of ACTH, either cosyntropin (Cortrosyn, Organon) or tetracosactrin (Synacthen, Alliance), should be used. Absorption of depot products such as ACTH gel cannot be relied on, particularly if the animal is collapsed or severely hypotensive. The protocol is described in Box 243-4.

In dogs and cats with hypoadrenocorticism, the resting cortisol concentration will be low or undetectable with a subnormal or negligible cortisol response to ACTH. About 85% of dogs with naturally occurring hypoadrenocorticism have basal and post-ACTH cortisol concentrations of less than 1.0 µg/dL (30 nmol/L) and more than 90% of cases have cortisol concentrations that do not exceed 2.0 µg/dL (60 nmol/L) at any time during the test.[37] Similar low cortisol concentrations have been reported in cats with hypoadrenocorticism. The ACTH stimulation test, however, does not distinguish between primary

hypoadrenocorticism and secondary hypoadrenocorticism due to pituitary failure or iatrogenic glucocorticoid administration.

243.7.7.2 Endogenous Plasma ACTH Concentration

Plasma ACTH concentrations are useful in distinguishing primary from secondary hypoadrenocorticism, but stringent and meticulous sample handling is crucial since the activity of ACTH in the plasma will reduce rapidly resulting in falsely low values and incorrect interpretation (see Box 243-4). Dogs and cats with primary hypoadrenocorticism have extremely increased endogenous ACTH concentrations (>500 pg/mL), due to the lack of a negative feedback of cortisol on the pituitary, whereas those with secondary hypoadrenocorticism have low or even undetectable concentrations of ACTH (<5 pg/mL).

243.7.7.3 Plasma Aldosterone Concentrations

Basal aldosterone concentrations are of little or no diagnostic value. Plasma aldosterone concentrations should be measured in response to ACTH stimulation (see Box 243-4). Theoretically, plasma aldosterone concentrations should help differentiate between primary hypoadrenocorticism (with reduced cortisol and aldosterone concentrations) and secondary hypoadrenocorticism (with normal aldosterone and reduced cortisol concentrations). However, aldosterone assays are not widely available and few studies have reported.

1619

1620

243.7.7.3.1 Box • 243-4 Protocols for Endocrine Tests for Hypoadrenocorticism

243.7.7.3.1.1 The ACTH Stimulation Test

- Collect 2 to 3 mL plasma or serum sample for basal cortisol concentration.*
- Inject 0.25 mg of synthetic ACTH (cosyntropin, Cortrosyn, Oganon: tetracosactrin; Synacthen, Alliance) intravenously to dogs or cats over 5 kg. Use only 0.125 mg in dogs or cats less than 5 kg.
- Collect a second sample for cortisol concentration 30 to 60 minutes later in the dog. In the cat, two samples should be collected at 60 and 90 to 120 minutes to ensure the peak response is measured.

243.7.7.3.1.2 Plasma Endogenous ACTH Concentration

- Blood (3 mL) is collected into a cooled plastic EDTA tube and centrifuged at 4° C immediately.
- The plasma should then be harvested and stored frozen (at less than −20° C) in a plastic tube.
- Samples must be transported to the laboratory frozen and must be kept frozen until assayed.
- Stringent and meticulous sample handling is crucial since hormone activity in the plasma will reduce rapidly resulting in falsely low values and incorrect interpretation.

- The endogenous ACTH assay must be validated for use in dogs and cats, otherwise the test may provide spurious results that could be misleading.

* The recent administration of glucocorticoids such as hydrocortisone, prednisolone, or prednisone may result in elevated cortisol concentrations due to cross-reactivity in many cortisol assays. For this reason glucocorticoids should be withheld for at least 24 hours before testing. There is no cross-reactivity with dexamethasone, but dexamethasone will suppress cortisol concentrations in animals with an intact hypothalamic-pituitary adrenal axis.

After stimulation with ACTH in normal dogs, plasma aldosterone concentrations should double, unless the basal concentration is already in the high-normal range.[38] In dogs suffering from primary hypoadrenocorticism with hypoaldosteronism, the basal aldosterone concentration is low with minimal or no increase in the post-ACTH aldosterone concentration. Some dogs with atypical Addison's disease have basal and post-ACTH aldosterone concentrations below the detectable limit of the assay despite the presence of normal serum sodium and potassium concentrations. Other dogs with atypical Addison's disease may have higher aldosterone concentrations than classical cases of hypoadrenocorticism both before and after ACTH stimulation, but concentrations are still abnormally decreased.

243.7.8 Treatment of Primary Hypoadrenocorticism

243.7.8.1 Acute Primary Hypoadrenocorticism

243.7.8.1.1 Intravenous saline

Hyperkalemia is life threatening in the acute Addisonian crisis but can be reliably treated with aggressive intravenous fluid therapy using normal saline (0.9% sodium chloride) at an initial rate of 60 to 80 mL/kg/hour for the first 1 to 2 hours. This treatment also helps in correcting the hypovolemia, hyponatremia, and hypochloremia. Urine output should be measured and if possible a central venous catheter should be used to monitor central venous pressure during fluid therapy. The response to treatment is often dramatic and other treatments for hyperkalemia such as glucose and insulin therapy or calcium administration are not usually required in animals with hypoadrenocorticism. The serum potassium decreases because of the dilution effect of the saline and the improvement in renal perfusion and glomerular filtration, which encourages further excretion of potassium into the urine. Although most cases respond quickly, generally within 12 hours, a few cases require intravenous fluid therapy over several days to correct the electrolyte imbalance and prerenal azotemia.

243.7.8.1.2 Intravenous glucose

If hypoglycemia is suspected, a 50% glucose solution should be added to the normal saline to produce a 5% dextrose solution. If hypoglycemia is known to be present, a bolus injection of 1 mL/kg of 50% glucose should be given intravenously initially before continuing with the 5% dextrose in 0.9% sodium chloride solution.

243.7.8.1.3 Glucocorticoid therapy

Glucocorticoid therapy should be used early in the treatment of the acute Addisonian crisis to correct hypocortisolemia. The glucocorticoids of choice in an acute crisis include the following:

hydrocortisone sodium succinate	10 mg/kg IV repeated every 3 to 6 hours or as a constant rate infusion at 0.5 mg/kg/hour[39]
prednisolone sodium succinate	5 mg/kg IV repeated every 3 to 6 hours
dexamethasone sodium phosphate	0.5 to 1.0 mg/kg IV given once

If possible, glucocorticoids should be withheld until after completion of the ACTH stimulation test since hydrocortisone and prednisolone have the potential to cross-react with cortisol in the assay falsely increasing the cortisol concentration. Dexamethasone can be used because it will not interfere with the cortisol assay and is recommended if glucocorticoid therapy cannot be delayed.

Mineralocorticoid preparations are not essential for treating an Addisonian crisis. However, mineralocorticoid therapy is recommended for any dog or cat suspected to have hypoadrenocorticism, once the ACTH stimulation test has been completed. As discussed, intravenous saline should help correct the hypovolemia, hyponatremia, hyperkalemia, and azotemia typical of this condition. No serious adverse reactions are associated with mineralocorticoid administration to non-hypoadrenal animals and the beneficial effects to those with the disease are complimentary to saline administration. Therefore it is recommended that desoxycorticosterone pivalate (DOCP; 2.2 mg/kg, IM) be administered. If the animal has hypoadrenocorticism, the drug will need to be given once again at 25 days, usually subcutaneously. The standard in management of these animals in crisis is administration of saline during completion of the ACTH stimulation test followed immediately by both glucocorticoid and mineralocorticoid therapy. Alternatives to DOCP have been tried. Hydrocortisone has been recommended as it possesses glucocorticoid and mineralocorticoid activities identical to those of endogenous cortisol.[39] Prednisolone also has some mineralocorticoid activity. Neither hydrocortisone or prednisolone have been shown to be superior to dexamethasone, which has no mineralocorticoid activity, in treating an Addisonian crisis (Table 243-1).

1620

1621

Table • 243-1 Relative Potencies of Adrenal Steroids

COMPOUND	GLUCOCORTICOID EFFECT	MINERALO-CORTICOID EFFECT
Cortisol/hydrocortisone	1	1
Prednisolone/prednisone	5	0.8
Dexamethasone	37	Negligible
Betamethasone	40	Negligible
Desoxycorticosterone	Negligible	50
Fludrocortisone	10–20	150
Aldosterone	0	500

243.7.8.2 Chronic Primary Hypoadrenocorticism (Maintenance Therapy)

243.7.8.2.1 Mineralocorticoid therapy

Dogs and cats with primary hypoadrenocorticism that have the classic electrolyte disturbances of hyponatremia, hyperkalemia, and hypochloremia, require lifelong treatment with mineralocorticoids.

Use of mineralocorticoid supplementation in those with atypical Addison's disease, where the electrolyte concentrations are normal, is more complex. In one study, two dogs with atypical primary hypoadrenocorticism were discharged on glucocorticoid supplementation only and both dogs died within 9 days of a presumed Addisonian crisis.[40] However, rarely some dogs with atypical primary hypoadrenocorticism have an isolated glucocorticoid deficiency and normal mineralocorticoid concentrations; these respond well to just glucocorticoid replacement therapy as do those with secondary hypoadrenocorticism.[26] Certainly it is prudent to try and differentiate primary and secondary hypoadrenocorticism or isolated glucocorticoid deficiency with plasma ACTH concentrations and basal and post-ACTH stimulated plasma aldosterone concentrations. While awaiting test results, it is recommended to administer both mineralocorticoid and glucocorticoid replacement therapy to reduce the possibility of an acute Addisonian crisis developing.

There are two preparations used for mineralocorticoid supplementation, fludrocortisone acetate, and desoxycorticosterone pivalate.

243.7.8.2.2

Fludrocortisone acetate (Florinef, Squibb)

Fludrocortisone is a potent oral synthetic adrenocortical steroid with mainly mineralocorticoid effects, although it retains some glucocorticoid activity. It is available in 0.1 mg tablets. An initial dose of 15 µg/kg of fludrocortisone is administered once daily. The response is monitored and serum electrolytes measured after 5 to 7 days. The dose rate should then be adjusted until the serum sodium and potassium concentrations are within the normal range. Frequently the dose of fludrocortisone has to be increased during the first 6 to 18 months of therapy to maintain normal electrolyte concentrations and in a few of these cases, fludrocortisone may have to be administered twice daily. In one study, the daily maintenance dose of fludrocortisone increased from an initial median dose of 13 µg/kg to a final median dose of 23 µg/kg.[40] In the same study, the final dose of fludrocortisone administered to more than half the dogs ranged from 15 to 30 µg/kg/day.

Adverse effects develop in some dogs, particularly those receiving high doses of fludrocortisone to maintain serum electrolyte concentrations within the normal range. These include mild signs of iatrogenic hyperadrenocorticism (i.e., polyuria, polydipsia, polyphagia, and weight gain) due to the glucocorticoid effects of fludrocortisone (see Table 243-1).

243.7.8.2.3

Desoxycorticosterone pivalate (Percorten-V, Novartis)

Desoxycorticosterone pivalate is a long acting ester of desoxycorticosterone acetate, a synthetic corticosteroid with only mineralocorticoid activity and no glucocorticoid activity. It is formulated into a microcrystalline suspension for injection. This preparation is not available in all countries, but studies have shown it to be effective in replacing the mineralocorticoid deficiency in dogs with hypoadrenocorticism.[41] It is considered the drug of choice in the United States (editor's note). The recommended dosage is 2.2 mg/kg intramuscularly or subcutaneously every 25 days. In another study, lower doses of between 1.4 and 1.9 mg/kg were found to be effective in controlling electrolyte concentrations and this study also showed that the interval between injections varied among dogs, ranging from 14 days to 35 days.[40]

Signs of iatrogenic hyperadrenocorticism have not been associated with long-term use of desoxycorticosterone pivalate since it possesses negligible glucocorticoid activity (see Table 243-1).

However, some dogs developed anorexia and depression in the presence of normal electrolyte concentrations, which resolved promptly with glucocorticoid replacement therapy.

243.7.8.2.4 Glucocorticoid therapy

The majority of dogs treated with fludrocortisone do not require daily glucocorticoid supplementation for maintenance therapy after the initial period of treatment. Those treated with DOCP should also be given glucocorticoids. Glucocorticoids at replacement dosages are administered for the first 1 to 2 weeks of treatment until the animal is stable and then gradually reduced. If glucocorticoid therapy is discontinued, owners of dogs and cats with hypoadrenocorticism should always be provided with a supply of prednisolone tablets to be given if the pet appears unwell (depressed, anorexic, or vomiting). Prednisolone at a dose of 0.1 to 0.2 mg/kg daily should be sufficient as glucocorticoid replacement for those animals that do require glucocorticoids. Higher doses are more likely to produce signs of iatrogenic hyperadrenocorticism.

243.7.8.2.5 Salt supplementation

Sodium chloride tablets or salting of the food should be instigated at a dose 0.1 mg/kg/day initially to help correct hyponatremia but can be phased out and is not usually required long-term in most cases. Dogs requiring unusually high doses of fludrocortisone, however, may respond to a lower dose of fludrocortisone if concurrently provided with salt supplementation.

243.7.9 Prognosis

The prognosis with hypoadrenocorticism is excellent when appropriate maintenance therapy has been used together with thorough owner education. In one study, the median survival time for dogs with hypoadrenocorticism was 4.7 years with a range 7 days to 11.8 years.[40] In this study, age, breed, and sex were not shown to influence survival time and no significant difference was found in the survival time of dogs treated with fludrocortisone compared with desoxycorticosterone pivalate. The long-term prognosis also appears to be excellent in cats, although fewer cases have been studied.[2]

243.8 SECONDARY HYPOADRENOCORTICISM

Secondary hypoadrenocorticism is associated with a deficiency of glucocorticoids caused by a deficiency in ACTH production and/or release. The production of mineralocorticoids, although reduced, generally remains adequate to control serum sodium and potassium concentrations.

1621 1622

243.8.1 Causes of Secondary Hypoadrenocorticism

Secondary hypoadrenocorticism can be associated with destructive lesions; for example, large nonfunctional tumors in the hypothalamus or pituitary. More commonly, however, it is an iatrogenic condition associated with prolonged suppression of ACTH by drug therapy with glucocorticoids or progestogens such as megestrol acetate.[42,43]

243.8.2 Clinical Signs

The clinical signs are variable, but may include depression, anorexia, occasional vomiting or diarrhea, weak pulse, and sudden collapse when stressed. If the secondary hypoadrenocorticism is associated with glucocorticoid therapy, then clinical signs of iatrogenic hyperadrenocorticism (Cushing's disease) are usually present.

243.8.3 Diagnosis

The diagnosis of secondary hypoadrenocorticism is based on a failure of the plasma cortisol concentrations to respond to ACTH stimulation together with low or undetectable endogenous plasma ACTH concentrations. If measured, the plasma aldosterone concentrations may be reduced, but basal concentrations will increase with ACTH stimulation.

243.8.4 Treatment

Glucocorticoid replacement, using prednisolone at a dose of 0.1 to 0.2 mg/kg daily is indicated for immediate correction of the clinical signs. Further treatment and the prognosis depend on the cause of the disease and whether it can be treated. Management of glucocorticoid therapy and the prevention of iatrogenic hyperadrenocorticism should be considered for all patients on long-term therapy with glucocorticoids or progestogens.

244 CHAPTER • 244 Gastrointestinal Endocrine Disease

Cynthia R. Ward

Robert J. Washabau

244.1 GASTROINTESTINAL ENDOCRINOLOGY

244.1.1 Endocrine, Neurocrine, and Paracrine Activation

A gastrointestinal (GI) hormone is classically defined as a substance that (1) is found in gastrointestinal endocrine cells, (2) is released by physiologic stimuli (e.g., feeding), (3) circulates in blood, (4) binds to a cell receptor at a distant site, and (5) evokes a biologic response.[1,2] However, the characterization of an event as the physiologic result of a hormonal action may be exceedingly difficult. It is now clear that many substances previously classified as gastrointestinal hormones are neither confined to the gastrointestinal tract nor solely blood-borne. For example, many of the peptides localized in GI endocrine cells (e.g., cholecystokinin, substance P, neurotensin, and somatostatin) also may be found in GI neurons and act as neurocrine substances.[3] As enteric neuropeptides, these substances may evoke similar or different biologic responses.

Some of these same peptides (e.g., cholecystokinin, substance P, somatostatin) are also located outside the enteric nervous system in vagal afferent fibers or central nervous system neurons. Thus some GI hormones may also function as enteric or brain neuropeptides. A further complication is that some GI endocrine cells may release peptides into the extracellular fluid from which they diffuse to, and directly act on, neighboring cells. Thus a GI peptide may evoke a biologic response through a paracrine mechanism of activation that operates independent of, or in parallel to, an endocrine mechanism of activation. Finally, some substances (e.g., somatostatin) may evoke biologic responses through endocrine, paracrine, and neurocrine mechanisms: endocrine regulation of gastric acid secretion, paracrine regulation of antral gastrin secretion, and neurocrine regulation of smooth muscle contraction.

Although it is clear that some GI peptides evoke biologic responses through an endocrine mechanism, it is equally clear that other GI peptides activate cells through a multitude of cellular pathways: endocrine, neurocrine, and paracrine. The endocrine, neurocrine, or paracrine status of each well-established gastrointestinal peptide and other bioactive substances is reviewed in this chapter. An overview of endocrine, neurocrine, and paracrine mediators may be found in Table 244-1.

244.1.2 Endocrine Substances and Endocrine Cell Types

Gastrointestinal endocrinology has developed from a small subset of endocrinology consisting of three distinct peptides (secretin, gastrin, cholecystokinin) with local secretagogue effects, to a biologic discipline made up of more than 100 bioactive peptides, all of which are expressed in a controlled cell-specific manner. This chapter reviews only those GI hormones (and enteric neuropeptides and paracrine mediators) for which there are clearly defined biologic functions. Just as knowledge of bioactive peptides has proliferated in recent years, so too has knowledge of the cell types that produce these substances. More than 20 different endocrine cell types have been identified in the GI tract, and the number continues to grow. Differences in cell type and lineage have been addressed in recent reviews.

244.1.3 Gastrointestinal Hormones

244.1.3.1 Gastrin-Cholecystokinin Family

GI hormones[1,2,4] and related peptides have been divided into structurally homologous families, one of which consists of gastrin and cholecystokinin (CCK). Gastrin and CCK share five basic characteristics: (1) partial sequence homology; (2) similar, but not identical, biologic activities; (3) heterogeneity—each hormone exists in different molecular forms; (4) ubiquity—each hormone is synthesized in different cell types; and (5) differential principality—different molecular forms predominate in different tissues and cells.[1,4,5]

244.1.3.1.1 Gastrin

Gastrin exists in several molecular forms that contain 34, 17, and 14 amino acids, respectively. G-34, also known as *big gastrin*, is the most abundant form of gastrin in serum. G-17, known as *little gastrin*, is less abundant than G-34 in serum but is much more potent in stimulating gastric acid secretion. Mini gastrin (G-14) has little biologic effect. Endocrine cells (G cells) in the gastric antrum and duodenum secrete gastrin in response to protein meals and, to a lesser extent, gastric distension.[1,4,5]

Table • 244-1 Overview of Endocrine, Neurocrine, and Paracrine Mediators

SUBSTANCE	PHYSIOLOGIC RELEASE	SITE OF ACTION	EFFECT
GI Hormones			
Gastrin	Intra-gastric peptides, gastric distension	Gastric parietal and chief cells	H^+ and pepsinogen secretion
		Pancreatic acinar cells	Enzyme secretion
		Stomach, duodenum, pancreas	Growth
Cholecystokinin	Duodenal fatty acids, amino acids, H^+	Gallbladder	Contraction
		Sphincter of Oddi	Relaxation
		Pancreas	Enzyme secretion and growth
		Stomach	Inhibition of gastric emptyingHCO_3^- and water secretion
Secretin	Duodenal H^+, fatty acids	Pancreatic duct cells, biliary epithelium, duodenum	
Oxyntomodulin	Ileal/colonic glucose and lipid	Gastric parietal cells	Inhibition of H^+ secretion
GLP-1	Duodenal fatty acids	Pancreatic islet (β) cells	Stimulates insulin secretion (incretin during euglycemia)
	Ileal fatty acids	Stomach	Inhibition of gastric emptying (“ileal brake”)
GLP-2	Carbohydrates, lipids, SCFA	Small intestine, colon	Inhibits gastric emptying (ileal brake) and secretion
			Crypt cell proliferation, suppression of apoptosis
			Reduces gut permeability and bacterial translocation
Gastric inhibitory polypeptide	Fatty acids, glucose, amino acids	Duodenum, jejunum, ileum	Inhibition of gastric and intestinal motility
			Stimulates insulin secretion (incretin during euglycemia)
Somatostatin	Lipids, protein, and bile	Stomach, intestine, pancreas	Inhibition of gastric, intestinal, and pancreatic secretion
Motilin	H^+ and lipids	Stomach, duodenum, jejunum	Increases GES pressure, stimulates propulsive motility
			Stimulates gastric, pancreatic, and biliary secretion
Neurotensin	Fatty acids	Stomach, pancreas, gallbladder	Stimulation of gastric and pancreatic secretion
			Gallbladder contraction
Pancreatic polypeptide	Protein, cholinergic reflexes	Pancreas	Inhibition of pancreatic enzyme and fluid secretion

Peptide YY	H^+ and lipids	Ileum and colon	Ileal brake, proliferation of gut mucosa
		Stomach and pancreas	Inhibition of secretion (H^+, pancreatic enzyme)
5-Hydroxytryptamine	H^+	Intestine and colon	Stimulation of motility and secretion
Ghrelin	Dietary protein	Pituitary	Stimulation of growth hormone secretion
Enteric Neuropeptides			
Substance P	Luminal distension, H^+, hyperosmolarity	Stomach, intestine, colon	Sphincteric contractions, intestinal peristalsis
		Pancreas	Stimulation of pancreatic enzyme secretion
Vasoactive intestinal polypeptide	Vagal stimulation	Stomach, intestine, colon	Increased blood flow, stimulation of fluid secretion
		Stomach, intestine, colon Pancreas	Relaxation of smooth muscle Stimulation of fluid and bicarbonate secretion
Opioids	Intestinal distension	Stomach, intestine, colon	Inhibition of longitudinal smooth muscle contraction Stimulation of circular smooth muscle contraction Inhibition of water and electrolyte secretion
Bombesins (GRP and Neuromedin B)	Vagal stimulation	Stomach	Stimulation of gastric acid secretion
		Pancreas	Stimulation of pancreatic enzyme secretion
		Gallbladder	Stimulation of gallbladder contraction
Somatostatin	Lipids and protein	Stomach, intestine, pancreas	Descending inhibitory reflex of peristalsis
Gastrin/CCK	Intestinal distension	Ileum and colon	Ileal and colonic contractions
Neuropeptide Y	Intestinal distension	Intestine and colon	Inhibition of intestinal motility
5-Hydroxytryptamine	H^+ and hypertonic solutions	Stomach, intestine, colon	Regulation of migrating myoelectric complex
Paracrine Mediators			
Histamine	Vagal stimulation	Stomach	Stimulation of gastric acid secretion
Somatostatin	Lipids and proteins	Stomach	Inhibition of gastrin secretion
		Pancreas	Regulation of insulin and glucagon secretion

Prostaglandins	H^+, gastric distension	Stomach	Stimulation of bicarbonate and glycoprotein secretion Stimulation of epithelial cell renewal and blood flow Inhibition of prostanoid receptors

CCK, cholecystokinin; *GES*, gastroesophageal sphincter; *GLP-1*, glucagon-like peptide-1; *GLP-2*, glucagons-like peptide-2; *GRP*, gastrin-releasing peptide; *SCFA*, small chain fatty acids.

The most important biologic action of gastrin is the stimulation of gastric acid secretion by gastric oxyntic (parietal) cells. A substantial fraction of the gastric acid secretory response to protein meals is, in fact, mediated by gastrin. However, interactions between gastrin, acetylcholine (neurocrine stimulant), and histamine (paracrine stimulant) determine the final gastric acid secretory output.[6] Most evidence suggests that the gastrin effect occurs through the bindingof gastrin to gastrin receptors on oxyntic cells, although one study suggests that the gastrin effect might be indirectly mediated through gastrin receptors on gastric mucosal immunocytes.[7]

1623

1625

Other important biologic actions of gastrin include stimulation of gastric pepsinogen secretion, gastric mucosal blood flow, antral motility, pancreatic enzyme secretion, and of pancreatic, gastric, and duodenal growth.[1,4,5,8] Pancreatic islet cells (delta cells) are a site of gastrin synthesis and secretion in fetal and neonatal animals.[8] Malignant transformation of these islet cells in adult animals results in functional gastrinomas. All but one of the gastrinomas that have been reported in the dog or cat have been of pancreatic origin (see Gastrinoma).

244.1.3.1.2

Cholecystokinin

Cholecystokinin (CCK) also exists in several molecular forms: CCK-63, CCK-58, CCK-39, CCK-33, CCK-12, CCK-8, and CCK-5. The predominant forms in serum are CCK-33, CCK-39, and CCK-58 and probably account for most of the GI hormone responses.[1,2,4] CCK-8 is the predominant form found in neurons and probably accounts for most of the enteric and central nervous system neuropeptide responses. Endocrine cells (I cells) in the duodenum and jejunum secrete CCK in response to intraduodenal fatty acids, amino acids, and H^+ ion.[1,2,4]

As a gastrointestinal hormone, CCK evokes several important biologic responses, most importantly, contraction of the gallbladder and stimulation of pancreatic enzyme secretion. Although CCK receptors have been demonstrated on both gallbladder smooth muscle cells and pancreatic acinar cells, it is now clear that CCK evokes gallbladder contraction and pancreatic enzyme secretion through activation of presynaptic cholinergic neurons at both sites.[4,8]

Other important endocrine actions of CCK include augmentation of pancreatic fluid secretion in the presence of secretin, relaxation of the sphincter of Oddi, inhibition of the gastric emptying of liquids, and stimulation of pancreatic growth.[1,4] Because CCK has trophic effects on pancreatic growth,[8] it has been suggested that canine juvenile pancreatic atrophy might result from CCK deficiency. However, CCK secretory deficiency was not observed in a group of young dogs with exocrine pancreatic insufficiency.[9] CCK has two important biologic actions as an enteric or brain neuropeptide (see Enteric Neuropeptides).

244.1.3.2 Secretin-Enteroglucagon-Gastric Inhibitory Polypeptide Family

Another structurally homologous group of GI hormones include secretin, enteroglucagon, gastric inhibitory polypeptide (GIP), as well as the enteric neuropeptides vasoactive intestinal polypeptide (VIP) and peptide histidine-isoleucine (PHI).

244.1.3.2.1 Secretin

Like gastrin and CCK, secretin exists in several molecular forms: 27-, 28-, 30-, and 71-amino acid polypeptides.[10] Acidification of the duodenum and jejunum by gastric H^+ is the most important stimulus for secretin secretion by endocrine cells (S cells) in the small intestine.[1,4] Intraduodenal lipid may also stimulate secretin release in some species. The most important biologic action of secretin is stimulation of secretion of a bicarbonate-rich pancreatic fluid from pancreatic ductal cells.[8,10] Pancreatic bicarbonate is important in neutralizing gastric acid delivered to the small intestine and in creating an alkaline environment that is close to the pH optimum of pancreatic lipase and colipase. Less important biologic actions of secretin are to stimulate secretion of bile bicarbonate and pancreatic enzymes.[1,8] The latter effect is observed only in the presence of CCK. Secretin has also been identified in brain neurons, but a functional role for secretin in these neurons has not yet been elucidated.

244.1.3.2.2 Enteroglucagon

Enteroglucagon and pancreatic glucagon arise from the same gene precursor through post-translational processing. Several molecular forms of enteroglucagon have been characterized, including enteroglucagon or oxyntomodulin, a 37 amino acid peptide; glicentin, a 69 amino acid, C-terminal extended form of oxyntomodulin; glucagon-like peptide (GLP)-1; intervening peptide-2; and GLP-2. Endocrine cells (L cells) in the terminal ileum and colon secrete enteroglucagon(s) in response to intraluminal glucose and lipid. The most important gastrointestinal action of the enteroglucagons is the inhibition of gastric acid secretion.[1,4] GLP peptides are also involved in the regulation of insulin secretion and glycemic control. GLP-1 is reported to stimulate proinsulin expression and to delay intestinal glucose absorption through inhibition of gastric emptying[11], thus acting as an incretin hormone during euglycemia to lower blood glucose. GLP-2 is a 33-amino acid peptide hormone released from intestinal endocrine cells following nutrient ingestion.[12] It exerts trophic effects on the small and large bowel epithelium via stimulation of cell proliferation and inhibition of apoptosis. GLP-2 also upregulates intestinal glucose transporter activity and reduces gastric motility and gastric secretion.[13]

244.1.3.2.3 Gastric inhibitory polypeptide (GIP)

GIP is a 54-amino acid peptide that exists in a single molecular form.[14] It is secreted by endocrine cells of the proximal small intestine in response to intraduodenal glucose, fatty acids, and amino acids. Two important biologic actions of GIP are inhibition of gastric acid secretion and stimulation of intestinal fluid secretion. The third, and likely most important, biologic action of GIP is the stimulation of pancreatic insulin release during hyperglycemia. It has been suggested that GIP and GLP-1 function as incretins and are the substances responsible for increased glucose disposal and enhanced insulin responses during intestinal absorption of glucose.[1,4,14]

244.1.3.3 Somatostatin

Somatostatin, or somatotropin release-inhibiting factor was originally isolated from the hypothalamus and found to inhibit growth hormone and thyrotropin release from the pituitary. Somatostatin was subsequently found in gut endocrine cells and gut neurons and shown to have endocrine, neurocrine, and paracrine biologic effects. Two molecular forms of somatostatin have been identified in gut endocrine cells: somatostatin-14 (SS-14), and somatostatin-28 (SS-28). Endocrine cells (D cells) throughout the GI tract secrete somatostatin in response to protein, lipid, and bile. As a GI hormone, somatostatin inhibits gastric acid and pepsin secretion, pancreatic enzyme and fluid secretion, gallbladder contraction, and intestinal amino acid and glucose absorption.[1,4] Synthetic forms of somatostatin (Sandostatin, Sandoz Pharmaceuticals) are available for the treatment of gastric acid secretory disorders.[15] In addition to its role as a gastrointestinal hormone, somatostatin also functions as an enteric neuropeptide (e.g., inhibition of intestinal motility) and as a paracrine substance (e.g., inhibition of gastrin secretion).

244.1.3.4 Motilin

Motilin is a 22-amino acid peptide found in endocrine cells of the proximal small intestine. Motilin secretion is stimulated by H^+ and lipid during the fed state. However, motilin secretion seems to be most important in the interdigestive (fasting) state. During fasting, motilin is episodically released into the serum and initiates phase III of the migrating motility complex (MMC, or interdigestive motility complex).[16] The MMC is a motility pattern that empties the stomach and small intestine of indigestible solids that accumulate during feeding. The cyclic release of motilin from the small intestinal mucosa during fasting is also thought to coordinate gastric, pancreatic, and biliary secretions with phase III of the MMC.[17] It has been shown that microbially ineffective doses of erythromycin (0.5 mg/lb or 1.0 mg/kg) initiate an MMC pattern that is indistinguishable from that induced by motilin. It has thus been suggested that erythromycin and other macrolide-like antibiotics might be useful gastric prokinetic agents.[18]

1625 1626

244.1.3.5 Neurotensin

Neurotensin is a 13-amino acid peptide, isolated from dog ileal and jejunal mucosal endocrine cells (N cells), for which no definitive endocrine function has been established. Intraluminal lipid stimulates neurotensin release from these endocrine cells. Neurotensin has been shown to inhibit gastric secretion and emptying, stimulate pancreatic secretion, and stimulate gallbladder contraction. One of the most likely potential roles of neurotensin is that of a physiologic enterogastrone that mediates inhibition of acid secretion after fat ingestion.[1,4]

244.1.3.6 Pancreatic Polypeptide

Pancreatic polypeptide (PP) is a 36-amino acid peptide that shares sequence homology with the enteric neuropeptide known as neuropeptide Y (NPY). PP is found exclusively in pancreatic islet cells (F cells). PP release is stimulated by protein meals and by cholinergic reflexes. The most important biologic action of PP is the inhibition of pancreatic enzyme and fluid secretion.[1,4] Islet cell PP secretion likely autoregulates acinar and ductal cell secretions because of the islet-acinar portal venous system. Other possible endocrine

functions of PP include relaxation of gallbladder smooth muscle, mild stimulation of gastric acid secretion, and initiation of the MMC along with motilin.[17]

244.1.3.7 Peptide YY

Peptide YY is a 36-amino acid peptide with structural similarities to PP and to NPY. Peptide YY may function as a physiologic enterogastrone similar to neurotensin in inhibiting pancreatic and gastric secretions.[1,4]

244.1.3.8 5-Hydroxytryptamine

5-Hydroxytryptamine (5-HT or serotonin) is found in endocrine cells (i.e., enterochromaffin cells) and enteric neurons throughout the gastrointestinal tract of most animal species.[1,2,4] In some species, 5-HT is also found in intestinal mucosal mast cells, pancreatic islet cells, and bronchial endocrine cells. 5-HT secreted by enterochromaffin cells may act through an endocrine or paracrine mechanism to stimulate gastrointestinal smooth muscle contraction and intestinal electrolyte secretion.[2] Tumors of these enterochromaffin cells (see Carcinoids) may be associated with hypermotility and secretory diarrhea because of the effects of 5-HT on motility and secretion.

244.1.3.9 Ghrelin

Ghrelin is a 28-amino acid octanoylated peptide found most abundantly in endocrine cells of the stomach.[18,19] It stimulates pituitary growth hormone (GH) secretion. *Ghre* is the Proto-Indo-European root for the word “growth,” and the suffix-*relin* signifies “releasing substances.” Ghrelin administration also has been shown to stimulate appetite, body growth, and fat deposition. The post-prandial gastric expression of ghrelin suggests a gastrointestinal-hypothalamaic-pituitary axis that influences GH secretion, body growth, and appetite that is responsive to nutritional and caloric intakes. Ghrelin and leptin may be the “ying and the yang” of a system that relays peripheral information to the brain and directs the body in the appropriate maintenance of energy reserves and nutritional intake.

244.1.4 Enteric Neuropeptides

A substance may be defined as an enteric neuropeptide if (1) it can be demonstrated histochemically in enteric neurons, (2) mechanisms for its biosynthesis exist in enteric neurons, (3) it is concentrated in nerve terminals, (4) it is released from nerve terminals by depolarizing stimuli through a calcium-dependent mechanism, and (5) mechanisms for the breakdown, re-uptake, or removal of the substance exist.[3]

244.1.4.1 The Tachykinins

The tachykinin family is represented by substance P, substance K, neuromedin K, physalaemin, kassinin, and eledoisin. Substance P is probably the most important enteric neuropeptide of this group. Substance P is distributed in enteric neurons throughout the GI tract and pancreas, and it is released from these neurons in response to luminal distension or depolarization. Substance P has three important biologic actions as an enteric neuropeptide.[3] First, it causes contraction of GI smooth muscle through an indirect effect of mediating cholinergic transmission and a direct effect on smooth muscle during the peristaltic reflex.

Second, substance P is located in primary sensory afferent fibers and may be important, along with calcitonin gene-related peptide in pain input to the central nervous system. Finally, substance P neurons stimulate pancreatic enzyme secretion from pancreatic acinar cells.

244.1.4.2 Vasoactive Intestinal Polypeptide/Peptide Histidine-Isoleucine

The classic enteric neuropeptides VIP and PHI share sequence homology with one another and with the GI hormones secretin, enteroglucagon, and GIP. VIP and PHI have many similar biologic activities and are derived from the same biosynthetic precursor. VIP and PHI are released by vagal stimulation and have four important biologic actions:[3] (1) stimulation of pancreatic fluid and bicarbonate secretion, (2) stimulation of salivary and intestinal fluid secretion, (3) increasing intestinal blood flow, and (4) relaxation of GI smooth muscle. This last property of VIP/PHI is felt to be important in descending intestinal inhibition (along with somatostatin) and in sphincter relaxation. Functional tumors of VIP-producing cells produce a watery diarrhea syndrome (pancreatic cholera or Verner-Morrison syndrome) in humans. This syndrome has not yet been described in dogs or cats.

244.1.4.3 Opioids

Opioid neurons are distributed throughout the gastrointestinal tract, spinal cord, brain, and adrenal glands. Methionine-enkephalin, leucine-enkephalin, and dynorphin are the most representative members of the opioid enteric neuropeptide family.[3] At least three different types of binding sites for these opioid peptides can be distinguished in the gut (μ, δ, and κ) but there may be others (ε and σ). The binding sites for these opioids are located on other neurons, smooth muscle cells, and epithelial cells. Opioid binding results in (1) inhibition of contraction of longitudinal smooth muscle through inhibition of acetylcholine release from myenteric plexus neurons; (2) direct stimulation of circular smooth muscle contraction; and (3) inhibition of intestinal water and electrolyte secretion through inhibition of submucosal plexus neurons. These effects account for the potent antidiarrheal properties of morphine and other opiate alkaloids that have been recognized for centuries.[3]

1626

1627

244.1.4.4 Bombesins

The bombesins are so-named because of their original isolation from the skin of the frog genus *Bombina*. The mammalian bombesins that have been identified as enteric neuropeptides are gastrin releasing peptide (GRP) and neuromedin B. GRP is released by vagal stimulation, and it stimulates gastrin release from antral G cells. Thus GRP acts a co-transmitter (along with acetylcholine) to stimulate gastrin release.[3,5] GRP also stimulates pancreatic acinar cell enzyme secretion.[3,8]

244.1.4.5 Somatostatin

In addition to its role as a gastrointestinal hormone, somatostatin (SS-14) has been identified as an enteric neuropeptide in neurons throughout the gastrointestinal tract. Somatostatin inhibits acetylcholine release from myenteric plexus neurons and may be involved in the descending inhibitory reflex of peristalsis.[3] Somatostatin neurons in the submucous plexus have a mucosal projection suggesting a further role for neuronal somatostatin in the control of mucosal function.

244.1.4.6 Gastrin-CCK

CCK-8 is an important enteric neuropeptide in the ileum and colon, especially in the cat. Intraluminal distension activates CCK-8-containing neurons, which then stimulate the release of acetylcholine from myenteric plexus neurons. CCK-8 thus acts as an excitatory transmitter in stimulating the peristaltic reflex in ileum and colon.[1,3] Brain CCK-8 neurons are involved in mediating the satiety response following feeding. Indeed, it has been suggested that human bulimia nervosa patients do not have normal satiety and have an impaired secretion of cholecystokinin in response to a meal.[20]

244.1.4.7 Pancreatic Polypeptides

A 36-amino acid peptide, NPY shares structural similarities with the GI hormones PP and peptide YY. Neurons that contain NPY decrease acetylcholine release from myenteric plexus neurons and hence inhibit small intestinal smooth muscle contraction.[3]

244.1.4.8 5-Hydroxytryptamine (5-HT or Serotonin)

In addition to its role as an endocrine/paracrine substance of the gastrointestinal tract, 5-HT is also found in enteric neurons, where it is believed to regulate the migrating myoelectrical complex and the intestinal peristaltic reflex.[3]

244.1.5 Paracrine Substances

A substance may be defined as having a paracrine mechanism of activation if (1) the substance is found within an effector cell, (2) receptors for the substance exist on an adjacent paracrine target cell, (3) the effector cell and paracrine target cell are in close proximity, and (4) the substance when applied to the paracrine target cell evokes a biologic response.[1,2] Histamine, somatostatin, adenosine, and prostaglandins have been shown to satisfy these criteria.

244.1.5.1 Histamine

Histamine is formed from the decarboxylation of histidine in mast cells found throughout the GI tract of dogs. In the dog, gastric mucosal histamine stores appear fully accounted for by mast cells, there being no evidence to indicate histamine is stored in endocrine cells.[6] Histamine released from mast cells diffuses into the interstitial milieu and is believed to bind parietal cell H_2 receptors to stimulate H^+ secretion.[6] A large body of evidence has accumulated in support of this idea, although one study suggests that the histamine effect might be indirectly mediated through histamine receptors on gastric mucosal immunocytes.[7] Regardless, H_2 receptor antagonists have been shown to be potent inhibitors of histamine, acetylcholine, and gastrin-stimulated H^+ secretion.

244.1.5.2 Somatostatin

The endocrine and neurocrine roles of somatostatin were discussed earlier in this chapter. As a paracrine substance, somatostatin has an important role in the inhibition of gastrin release. Somatostatin cells in the gastric antrum have long cytoplasmic processes that terminate adjacent to antral G cells. Paracrine release of somatostatin by these somatostatin cells is postulated to mediate the negative feedback inhibition of H^+ on gastrin release.[21] Somatostatin released from pancreatic islet cells (D cells) may also auto-regulate pancreatic insulin and glucagon secretion through a local paracrine mechanism.[22]

244.1.5.3 Prostaglandins

Prostaglandins are long chain fatty acids that are distributed throughout the GI tract. The role of prostaglandins as paracrine substances is perhaps best understood in the gastric mucosa, where they bind to inhibitory prostanoid receptors on gastric oxyntic cells. These receptors are coupled to inhibitory G proteins and subsequent inhibition of adenylate cyclase and H^+ secretion.[23] A "cytoprotective effect" of prostaglandins, separate from the direct inhibition of acid inhibition, has also been implied. Gastric prostaglandins, for example, stimulate mucosal bicarbonate and glycoprotein secretion, epithelial cell renewal, and mucosal blood flow. These effects are all central to the barrier properties of the gastric mucosa.[24] Synthetic forms of prostaglandins (Cytotec, Searle) are now available for the therapy of gastric mucosal barrier disorders.[25,26,27]

244.2 DISEASES OF THE GASTROINTESTINAL ENDOCRINE SYSTEM

In small animals, the major syndromes of gastrointestinal endocrine pathology are diabetes mellitus, pancreatic islet cell tumors, and intestinal carcinoid. The syndromes of glucagonoma, gastrinoma, carcinoid, and pancreatic polypeptidoma are reviewed.

244.2.1 Glucagonoma

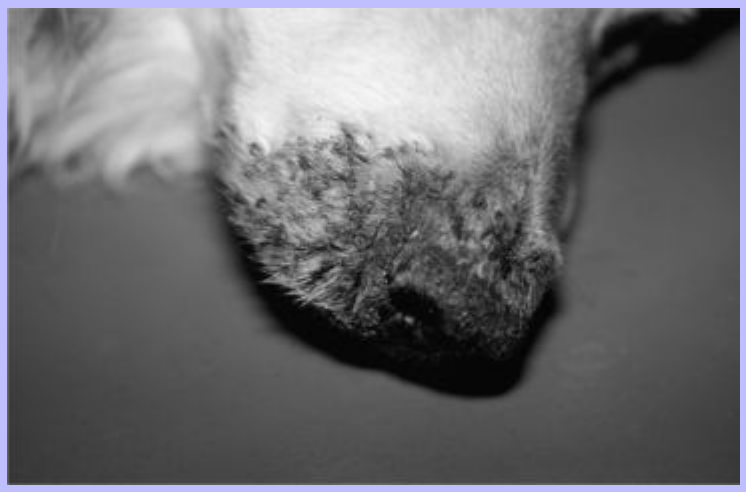
Glucagonoma is a rare tumor of the pancreatic alpha cells in dogs and humans. There are no reports of this disease in the cat. It is characterized by a crusting skin rash, termed *necrolytic migratory erythema* (NME) and glucose intolerance or overt diabetes mellitus (Figure 244-1). Increased serum glucagon concentrations stimulate hepatic amino acid turnover, gluconeogenesis, and glycogenolysis. In dogs, it is definitively diagnosed by immunohistochemistry of excised pancreatic tumor tissue.

244.2.2 Signalment and Clinical Signs

Eight dogs with presumptive or definitively diagnosed glucagonoma have been reported.[28–34] These eight dogs included seven breeds, four females, and four males, and their ages ranged from 5 to 13 years.

In human glucagonoma patients, NME is virtually pathognomonic for the disease. Although NME has been identified in all dogs with glucagonoma, it is more commonly associated with liver disease. Glucose intolerance or overt diabetes mellitus is also found in humans with glucagonoma and is caused by excess gluconeogenesis and glycogenolysis resulting from increased plasma glucagon concentrations. Other clinical signs in people include weight loss, anemia, diarrhea, stomatitis, and thromboembolic disease.

Figure 244-1 Necrolytic migratory erythema of the muzzle of a dog with glucagonoma. (Courtesy William H. Miller, Jr.)



Dogs with glucagonoma had 3-week to 16-month histories of crusting dermatologic lesions with or without ulceration or erosion at the time of presentation. Footpad lesions were present in all dogs with other affected sites including the elbows, hocks, nose, mucocutaneous junctions of the mouth or eyes, prepuce, vulva, scrotum, flank, ventral abdomen, and distal extremities. One dog also had oral ulcerations. Other clinical signs or physical exam findings at the time of initial presentation included lethargy, weight loss, decreased appetite, muscle atrophy, and peripheral lymphadenopathy. One dog also had palpable hepatomegaly.

244.2.2.1 Laboratory and Imaging Findings

Laboratory abnormalities included hyperglycemia (five dogs), nonregenerative anemia (three dogs), mild to moderately increased ALT activity (four dogs), mild to moderately increased ALP activity (three dogs), decreased albumin (two dogs), decreased globulin (one dog), decreased BUN (two dogs), decreased cholesterol (one dog), and glucosuria (two dogs). Liver function tests, including serum bile acid measurements (six dogs) and ammonia tolerance test (one dog), were normal. One dog had an ACTH stimulation test supportive of hyperadrenocorticism.

One or more imaging studies were performed in all dogs. Abdominal radiographs were unremarkable in all dogs. Abdominal ultrasound was normal in three dogs but revealed liver lesions in four dogs and a possible pancreatic mass in one dog. Liver abnormalities on ultrasound included a small liver with increased echogenicity of the portal and hepatic vein walls, diffuse hyperechogenicity, multiple small hypoechoic foci, and a single well-defined hyperechoic area. A mass in the left pancreatic limb was visualized by computed tomography in one case.

244.2.2.2 Diagnosis

Diagnosis in people is confirmed by demonstration of increased plasma glucagon concentrations and a pancreatic islet cell tumor that shows positive immunoreactivity for glucagon.

244.2.2.2.1 Glucagon measurement

Demonstration of increased circulating glucagon concentrations is important to establish the hypersecretion of glucagon by the tumor cells and to associate clinical signs with excess hormone secretion. Plasma glucagon concentrations of more than 1000 ng/L are considered diagnostic of the disease in people. Plasma glucagon concentrations were measured in six of the eight dogs reported in the literature. In all dogs plasma glucagon concentrations were increased, ranging from 1.6 to 10.1 times the upper limit of reference ranges. It is important to note, however, that syndromes other than glucagonoma may be associated with increased plasma circulating glucagon, including acute pancreatitis, hypercortisolism, hepatic failure, and renal failure. Because of the paucity of cases in the veterinary literature, it is difficult to determine plasma glucagon concentrations that are diagnostic of glucagonoma in the dog. The presence of concurrent disease, as noted above, should always be considered.

244.2.2.2.2 Plasma amino acid concentrations

Hypoaminoacidemia is often found in humans with glucagonoma and is thought to result from increased hepatic conversion of amino acid nitrogen into urea nitrogen by the excess glucagon.[35] Plasma amino acids were measured in three of the dogs reported and were decreased in all three (20 of 24, 13 of 18, and 4 of 5 amino acids determined). Arginine, histidine, and lysine concentrations were consistently decreased, although it must be noted that complete amino acid profiles were not measured in all cases.

244.2.2.3 Pathology

Most glucagon secreting tumors in people occur singly and are quite large (5 to 10 cm) at the time of diagnosis. Up to 82% are metastatic. In dogs, the diagnosis of glucagonoma has relied on demonstration of a primary pancreatic or metastatic tumor that stains positively for glucagon immunoreactivity. Pancreatic tumors were found in seven of the eight dogs reported. In one animal, serial sections of the pancreas failed to reveal neoplasia; diagnosis was instead based on positive glucagon immunoreactivity of metastatic tissue in the liver in conjunction with hyperglucagonemia. Location of pancreatic tumors included the right lobe (three dogs), left lobe (two dogs), body (one dog). As in the human, metastasis of glucagonoma is common in dogs and occurred in five of the eight cases. The liver was the most frequently affected site (four of the eight dogs) with one dog showing metastasis to a regional lymph node. Lymph node or liver tissue was not obtained in all cases so that the rate of metastasis may be higher than reported.

Glucagon immunohistochemical staining was performed on primary pancreatic and/or metastatic tumors. In most cases, tissue sections were also stained for immunoreactivity to somatostatin, gastrin islet amyloid polypeptide, insulin, pancreatic polypeptide, and/or synaptophysin, a marker for neuroendocrine cells.[36] In accordance with diagnostic criteria, all primary and metastatic tumors stained positively for glucagon immunoreactivity. In five dogs, primary tumor or metastatic tissue stained positively for one or more of above listed peptides. In some cases, metastatic tissue had different immunoreactivity than the primary tumor.

244.2.2.4 Therapy

Surgical resection or debulking is the treatment of choice for glucagonoma. In people removal of the glucagon-secreting tumor resolves the skin rash and other clinical signs. In the dogs with glucagonoma,

four had surgical resection of the pancreatic mass. Two of these animals were euthanized 3 days after surgery because of presumed acute pancreatitis. One dog with metastatic disease of a mesenteric lymph node had surgical resection of both the lymph node and pancreatic mass. Glucagon concentrations decreased into the reference range the day following surgery and remained normal for 3 months. Plasma amino acid concentrations also increased within 30 days, and cutaneous lesions resolved within 45 days of surgery. Nine months after surgery, the dog was euthanized due to the development of new skin lesions. A second dog with metastasis to the liver had mild improvement of skin lesions following surgical resection of the pancreatic mass. Plasma glucagon concentrations, however, remained increased 10 days following surgery, but the dog was well 4 months post surgery.

1628

1629

Medical therapy should be considered as an adjunct for surgical resection in dogs with metastasis or for palliative therapy if surgery is not performed. Long-acting somatostatin analogues such as octreotide have been used to control plasma glucagon concentrations and clinical signs in humans. In one report, somatostatin was administered at a dosage of 6 μg/kg subcutaneously every 8 hours to a dog with metastatic disease, and marked improvement in skin lesions was reported within 14 days.[37] The treatment was not continued due to expense, and the dog was euthanized. Chemotherapeutic agents such as streptozotocin with 5-fluorouracil and dacarbazine have been somewhat successful in human treatment.[38] Intravenous amino acid therapy has also been helpful in some humans for the dermatologic abnormalities. There are no data on use of these agents in dogs.

Humans with glucagonoma often have concurrent diabetes mellitus. Some can be controlled by diet or oral hypoglycemic agents; however, many require insulin therapy.[39] Five of the eight dogs with glucagonoma had mild to moderate hyperglycemia with or without glucosuria. Two of these dogs were treated with insulin, one of which no longer required insulin 10 days after treatment was instituted. No long-term use of insulin in dogs with glucagonoma has been reported.

244.2.2.5 Prognosis

Because dogs have had metastatic disease at the time of diagnosis, prognosis is poor. Moreover, surgical outcome appears to be further complicated by the occurrence of pancreatitis. NME (also referred to as *superficial necrolytic dermatitis, hepatocutaneous syndrome,* and *metabolic epidermal necrosis*) is found more commonly in dogs with hepatic disease; glucagonoma accounts for less than 10% of the cases of NME. Therefore it is essential to assess liver function in dogs with NME so that a precise etiology may be determined and treatment options and prognosis correctly presented. Serum liver enzyme activities were abnormal in most dogs with glucagonoma; however, liver function tests were normal in all dogs tested.

Abdominal radiography and ultrasonography were found to be poor methods for detecting canine pancreatic glucagonoma. Computed tomography successfully identified the pancreatic glucagonoma in one dog and may prove more useful in the diagnosis of this disease. As clinical awareness and diagnostic testing improve, our understanding of the disease and treatment outcomes will undoubtedly improve as well.

244.2.3 Gastrinoma

In 1955 Zollinger and Ellison described a syndrome in people of gastric acid hypersecretion, severe peptic ulceration, and pancreatic islet cell tumor that was eponymously termed the *Zollinger-Ellison syndrome*. These islet cell tumors were subsequently demonstrated to secrete excessive amounts of gastrin and are now more appropriately called *gastrinomas*. Clinical signs result from excess plasma gastrin concentrations causing

gastric acid hypersecretion. Hypergastrinemia and gastric hyperacidity result in gastrointestinal inflammation and ulceration, maldigestion, and hypertrophy of gastric mucosa.

244.2.3.1 Signalment and Clinical Signs

Gastrinomas are uncommon and have been reported in 30 dogs and in three cats.[40–53] They occur in middle-aged dogs (average age 8.2 years; range 3.5 to 12 years). Cats ranged in age from 10 to 12 years. No breed predilection is noted, and females may be at slightly greater risk. The most frequent clinical signs have been vomiting and weight loss. Depression, lethargy, anorexia, and intermittent diarrhea are also commonly reported. Less frequent clinical signs include melena, abdominal pain, polydipsia, hematemesis, hematochezia, and obstipation. Physical examination findings are often nonremarkable in the early stages of the disease. However, abdominal pain, fever, tachycardia, pale mucous membranes, and dehydration may occur in extremely sick animals as a result of severe gastrointestinal ulceration or perforation. A palpable abdominal mass was reported in one cat.

Clinical signs result from gastrin-induced gastric acid hypersecretion and gastric mucosal hyperplasia. Hypersecretion and hyperplasia may result in gastric ulceration and gastric outflow obstruction. Gastroesophageal acid reflux may cause severe esophagitis and/or ulceration. Diarrhea and steatorrhea are caused by the large amount of acidic fluid entering the duodenum and jejunum and by the increased circulating concentrations of gastrin that reduce intestinal water and ion absorption.

244.2.3.2 Laboratory Findings

The CBC may reveal a regenerative anemia presumably due to gastrointestinal bleeding. Gastrointestinal inflammation may elicit a leukocytosis and neutrophilia with or without a left shift. One dog with concurrent myelofibrosis had a nonregenerative anemia. Biochemical abnormalities include hypoalbuminemia, hypoproteinemia, hypokalemia, hypochloremia, hyponatremia, metabolic alkalosis, hyperbilirubinemia, and mild increases in serum liver enzyme activities. Hypoalbuminemia and hypoproteinemia are due to loss of protein through an ulcerated gastrointestinal mucosa. Persistent vomiting in dogs and cats with gastrinoma results in hypokalemia, hyponatremia, hypochloremia, and metabolic alkalosis. Diarrhea and reduced food intake could also contribute to the hypokalemia. Hyper-and hypoglycemia have also been infrequently reported and may be due to concurrent hypersecretion of corticotropin or insulin, respectively; in one dog with hyperglycemia, extracts of the islet tumor revealed adrenocorticotropic hormone in addition to gastrin. Increases in serum liver enzyme activities and bilirubin may reflect tumor metastasis to the liver that is commonly found in these cases.

244.2.3.3 Imaging Findings

Survey abdominal radiographs are usually unremarkable or they may reveal loss of abdominal detail and/or ascites with gastrointestinal perforation. Contrast-enhanced radiographic studies may show evidence of gastroduodenal ulceration, prominent gastric rugal folds, thickened pyloric antrum, complete pyloric obstruction, or rapid small bowel transit time. Abdominal ultrasound may reveal gastric ulcer, thickened gastric wall or pylorus, or evidence of metastasis in the liver or regional lymph nodes. Gastrinomas are generally small in size and difficult to directly visualize by abdominal ultrasonography. Wider use of other imaging modalities such as endoscopic ultrasound, magnetic resonance imaging, and computed tomography undoubtedly increase diagnostic sensitivity;[54,55] however, no studies have been reported using these techniques on animals.

244.2.3.4 Endoscopic Findings

Endoscopy was performed on half of the dogs reported. Abnormalities noted were esophageal inflammation or ulceration, thickened gastric rugae, gastric ulceration or hemorrhage, excessive fluid in the stomach, hypertrophied pyloric antrum, and duodenal ulceration. Histological examination of endoscopically derived biopsy samples of thickened gastric mucosa or mural lesions may be relatively normal. In this case surgically obtained, full-thickness biopsy samples should be considered.

1629

1630

244.2.3.5 Diagnosis

Clinical tests to support a diagnosis of gastrinoma include measurement of basal gastric acid secretion and serum gastrin concentration, provocative tests such as secretin and calcium stimulation, and somatostatin receptor scintigraphy. Demonstration of appropriate histopathological and immunohistochemical evidence from excised pancreatic tumor or metastatic tissue is necessary to confirm the diagnosis.

244.2.3.5.1 Basal gastric acid secretion

This test is commonly performed in humans and is abnormally increased in more than 80% of humans with gastrinoma.[38,56] This test has been performed in four dogs with gastrinoma. Gastric pH was low (pH = 0.99, 1.0, 1.0, 1.5) in all four dogs and was correlated with increased basal acid secretion in two of the dogs.

244.2.3.5.2 Basal serum gastrin concentration

This is considered the best screening test for gastrinoma in humans and is abnormal in more than 98% of those with gastrinoma. In dogs and cats with histologic evidence of gastrinoma, measured basal serum gastrin concentrations have been greater than three times the highest value in the reference range. However, other disease syndromes may be associated with increased basal serum gastrin concentrations including renal failure, gastric outflow obstruction, chronic gastritis, liver disease, and drugs that remove the negative feedback inhibition of acid on gastrin secretion, including antacids, H_2 receptor blockers, proton pump inhibitors, and glucocorticoids. Therefore this test cannot be relied upon as a sole diagnostic test, even if these other conditions can be ruled out. In humans with gastrinoma, basal serum gastrin concentrations more than 1000 ng/L combined with gastric pH less than 2.5 is diagnostic for gastrinoma without further testing. Due to the paucity of cases in the veterinary literature, basal serum gastrin concentrations diagnostic for gastrinoma (versus other diseases or drug therapy) have not yet been established.

244.2.3.5.3 Secretin stimulation

The preferred provocative test to diagnose gastrinoma in people is secretin stimulation. Secretin will stimulate gastrin secretion in patients with gastrinoma but not in healthy people. This test has been performed in three dogs with gastrinoma and one dog with pancreatic polypeptidoma, and therefore data regarding testing procedure and interpretation is limited. In dogs, serum samples should be collected before and 2, 5, 10, and 30 minutes following intravenous administration of 2 to 4 U/kg of secretin. The 2-and 5-minute samples are thought to be the most diagnostic. In humans a twofold or greater increase in serum gastrin following secretin administration is diagnostic for gastrinoma. In those animals that have

been tested, two dogs had a greater than twofold increase in gastrin and one dog had a 1.4-fold increase within 5 minutes of secretin administration. One dog diagnosed with pancreatic polypeptidoma had a transient fasting hypergastrinemia, but no response to secretin stimulation.

244.2.3.5.4 Calcium stimulation

Similar to secretin, calcium infusion stimulates an increase in serum gastrin concentrations in humans with gastrinoma, whereas serum gastrin concentrations are unchanged unaffected individuals. This test has been used in two dogs with gastrinoma and one dog with pancreatic polypeptidoma. Calcium is administered as an intravenous bolus of 2 mg/kg over 1 minute. Serum samples are collected before and 15, 30, 60, 90, and 120 minutes after calcium administration. Using this protocol, both of the gastrinoma dogs had a twofold increase in serum gastrin concentration in response to calcium infusion. Such an increase supports a diagnosis of gastrinoma in humans. The dog with pancreatic polypeptidoma, had normal serum gastrin concentrations after calcium infusion. Because of the dangers of intravenous calcium infusion, this test should be used with caution.

244.2.3.6 Pathology

A definitive diagnosis of gastrinoma requires the findings of hypergastrinemia, histopathologic evidence of pancreatic islet cell neoplasia, and immunohistochemical evidence of gastrin in neoplastic islet cells. The presence of hormones in endocrine tumor tissue alone does not necessarily guarantee their excessive secretion into the circulation. In dogs, gastrin-secreting tumors have been reported most frequently in the right lobe and body of the pancreas. Most animals had solitary nodules, but multiple masses have been reported. At the time of diagnosis, the gastrinoma had metastasized in 85% of cases, usually to the liver. Other metastatic sites included, spleen, lymph nodes, mesentery, omentum, peritoneum, and serosal surfaces of the duodenum and jejunum. The presence of gastrin in the tumors can be documented by immunohistochemistry or by radioimmunoassay of extracts from tumor tissue. Ultrastructural studies to detect unique intracytoplasmic granules can also be used to confirm gastrinoma; however, this requires electron microscopic techniques that may be cost prohibitive. Other pathological findings of dogs and cats with gastrinoma included perforating and nonperforating ulceration (95% of cases) of the esophagus, stomach, duodenum, and jejunum. Gastric hypertrophy, thyroid C-cell hyperplasia, thyroid follicular cell carcinoma, and adrenal hyperplasia have also been reported.

244.2.3.7 Therapy

Treatment of gastrinoma is directed toward surgical resection or reduction of the gastrinoma and/or metastases and medical control of gastrin secretion from the tumor cells. Adjunct medical therapy includes treatment of gastric acid hypersecretion, gastrointestinal ulceration, and fluid and electrolyte losses.[57]

244.2.3.7.1 Treatment directed at tumor cells

Surgical resection of gastrinomas can prove challenging since the primary tumors are small and difficult to localize. Tumor localization with imaging modalities such as endoscopic ultrasound, computed tomography, or magnetic resonance imaging are usually more sensitive than abdominal ultrasound and are used more successfully in humans. Somatostatin receptor scintigraphy, using a somatostatin analogues (e.g., ^{111}Indium octreotide or pentetreotide) to detect somatostatin receptors present on gastrinoma cells is a sensitive test used to localize tumors and metastases in people. Positive receptor

binding can also predict successful medical treatment of gastrinoma with somatostatin analogues. This technique has been reported in one dog in which 2 mCi of the octreotide analogue was used and images successfully generated by gamma camera imaging.[43] Careful digital palpation of the pancreas, liver, and surrounding areas should be performed if the tumor cannot be visualized at surgery; intraoperative pancreatic ultrasound may be beneficial. The pancreas should be handled carefully and pancreatic blood flow should be preserved to avoid postoperative pancreatitis. Because metastasis is common at the time of surgery, the liver, lymph nodes, spleen, duodenum, mesentery, and omentum should be inspected and biopsied as appropriate. Metastatic foci should also be resected, as possible, since this can provide palliation for the patient. As these tumors are slow growing, debulking may provide relief from clinical signs.

1630

1631

Following pancreatic resection or manipulation, the animal should be managed as if it had acute pancreatitis, with fluid support, extensive monitoring, and restriction of food or water by mouth. Administration of octreotide, a somatostatin analogue, pre-and post-operatively has been suggested to decrease pancreatic gastrin and gastric acid secretion.[53]

244.2.3.7.2 Somatostatin analogues

Somatostatin inhibits gastrin and hydrogen ion secretion in gastrinomas and in gastric parietal cells. A long-acting somatostatin analogue, octreotide, has been used in two dogs with gastrinoma. Doses started at 2 μg/kg twice per day and were increased to 10 to 20 μg/kg three times per day. The dogs were maintained on this therapy for 10 to 14 months. One dog relapsed after the medication was discontinued. The other dog showed marked response to treatment after the dosing was increased to three times per day. At necropsy, one dog showed marked increase of tumor growth and metastasis. Unfortunately, the expense of this drug may limit its use. Successful treatment of gastrinoma with chemotherapeutic drugs has not been reported.

244.2.3.7.3 Adjunct medical therapy

244.2.3.7.3.1 Gastric hyperacidity

As gastrinomas are slow growing, medical therapy to control the major clinical signs of gastric hyperacidity and gastrointestinal ulceration may provide significant palliation for dogs and cats.[57] Because of the high rate of metastasis, gastrin secretion in most animals remain increased after surgery, and these dogs and cats suffer from continuing gastric hyperacidity. Adjunct therapy should be started immediately to prevent the development of perforating ulcers. The most common agents used to control gastric hyperacidity in veterinary medicine are the H_2 receptor antagonists such as cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid). See Box 244-1 for dosages and dosing intervals. They are potent inhibitors of H^+ secretion in dogs and cats. Success with cimetidine therapy has been reported in several dogs and one cat with gastrinoma. It has been suggested that animals unresponsive to standard doses of gastric acid secretory inhibitors may respond to higher doses and/or dual agent therapy.[53]

Omeprazole (Prilosec) is an inhibitor of parietal cell H^+, K^+-ATPase and reduces gastric acid secretion with a long duration of action in normal dogs.[57] Two dogs with gastrinoma have been successfully treated with omeprazole. In one case, omeprazole controlled gastrointestinal signs that

were unresponsive to treatment with cimetidine and sucralfate. This dog remained asymptomatic for more than 2 years. Omeprazole may be the better choice for control of gastric hyperacidity either in place of or in addition to H_2 receptor antagonists but it should be emphasized that there is no evidence-based medicine in support of either drug classification.

244.2.3.7.3.2 Gastrointestinal ulceration

Treatment of gastrointestinal ulceration includes surgical resection and control of gastric hyperacidity as discussed. The use of diffusion barriers and cytoprotective agents is discussed here. Dosages and dosing regimes are presented in the Drug Index (see Box 244-1).

Sucralfate (Carafate) is an example of a diffusion barrier used to promote ulcer healing. It is a complex of sulfated sucrose and aluminum hydroxide that reacts with gastric acid and binds to necrotic tissue proteins. Misoprostol (Cytotec) is a 16,16-dimethylated synthetic prostaglandin that has cytoprotective properties in addition to its direct acid-inhibitory effect. Synthetic prostaglandins may be useful in restoring the protective properties of the gastric mucosal barrier in ulcer patients, although the beneficial effects of this classification of agents have not yet been unequivocally established in evidence-based medicine type studies.[57]

244.2.3.7.3.2.1 Box • 244-1 Drug Index

244.2.3.7.3.2.1.1 Histamine (H_2) Receptor Antagonists

Cimetidine (Tagamet-SmithKline Beecham), 2 to 4 mg/lb (5 to 10 mg/kg) PO, SQ, IV q6h or q8h

Ranitidine (Zantac-Glaxo), 0.5 to 1.0 mg/lb (1 to 2 mg/kg) PO, SQ, IV q8h or q12h

Famotidine (Pepcid-Johnson & Johnson, Merck Consumer), 0.1 to 0.5/mg/kg PO, IV q12h

Nizatidine (Axid-Eli Lilly), 1.0 to 3.0 mg/kg SQ, IM, IV q8h

244.2.3.7.3.2.1.2 H^+, K^+-ATPase Inhibitors

Omeprazole (Losec-MerckSharp & Dohme) 0.35 mg/lb (0.7 mg/kg) PO q24h

244.2.3.7.3.2.1.3 Diffusion Barriers

Sucralfate (Carafate-Marion), 1 g q8h for large dogs 0.5 g q8h for smaller dogs 0.25 to 0.5 g q8h to q12h for cats

244.2.3.7.3.2.1.4 Synthetic Prostaglandins

Misoprostol (Cytotec-Searle), 2 to 5 µg/kg PO q8-12 h

244.2.3.7.3.2.1.5 Somostatin Analogs

Octreotide (Sandostatin-Novartis), 2 to 8 µg/kg SC q8-12h

244.2.3.8 Prognosis

Long-term prognosis in dogs and cats with gastrinomas is grave since metastatic disease is present in 85% at the time of surgery. In animals that underwent surgery and medical management, survival times ranged from 1 week to 18 months. The prognosis is likely to improve with increased awareness and diagnostic techniques for tumor localization. The availability and affordability of anti-secretory drugs and therapies to reduce gastric hyperacidity and promote ulcer healing will also promote longevity in animals with gastrinoma.

244.2.4 Intestinal Carcinoid

Intestinal carcinoid is a rare tumor arising from enterochromaffin cells that can be found in the tracheobronchial epithelium, pancreatic ducts, biliary tree, genitourinary tract, stomach, and intestine. In people they are classified according to their location and ability to secrete vasoactive amines. People with carcinoid tumors can develop carcinoid syndrome that manifests as facial flushing, abdominal cramping, bronchoconstriction, and diarrhea. Clinical signs are related to the excessive secretion of 5-hydroxytryptamine (serotonin) from the neoplastic enterochromaffin cells.

Carcinoid tumors have been described in 25 dogs and four cats. In dogs this tumor has been found in the liver (15), stomach (1), duodenum (2), cecum (1), ileocecal junction (1), colon (2), rectum (2) and gall bladder (1).[58–64] In cats they have been localized to the stomach, pancreas, intestine, and liver.[65–68] Metastasis was common at the time of diagnosis with sites including liver, lymph nodes, lung, spleen, adrenal glands, and mesentery. A functional carcinoid syndrome as reported in humans has not been recognized in cats and dogs. Most animals had clinical signs relating to structural effects of the tumor or generalized disease related to neoplasia. The most common clinical signs were anorexia, vomiting, weight loss, and gastrointestinal bleeding. Diarrhea was less common.

1631

1632

In veterinary medicine, diagnosis is confirmed by histopathologic and ultrastructural examination of the tumors. Diagnosis in people relies on several factors including measurement of plasma and urinary serotonin levels or its metabolites. Such tests have not been reported in veterinary patients. Most animals were diagnosed upon postmortem examination. Surgical resection was successful in a recent case report in a cat that remained disease free for 4 months before succumbing to an unrelated disease. Although these tumors are slow growing, metastasis is common at diagnosis; therefore prognosis is guarded.

244.2.5 Pancreatic Polypeptidoma

Pancreatic polypeptide is commonly found by immunohistochemical staining in human and canine pancreatic endocrine tumors that secrete other enteric hormones such as gastrin, glucagon, or insulin. The significance of its presence in these cells is unknown, and increased plasma pancreatic peptide concentrations have been documented rarely in humans. These patients do not display a characteristic clinical syndrome; however, secretory diarrhea and a macular rash may be associated with excess pancreatic polypeptide secretion from polypeptidomas. There has been one report in the veterinary literature implicating pancreatic polypeptidoma in clinical disease.[69]

In this case a 7-year-old FS cocker spaniel had chronic vomiting, hypertrophic gastritis, duodenal ulceration, and pancreatic adenocarcinoma with hepatic metastasis. Plasma PP concentrations were extremely high in this dog. Neoplastic tissues obtained at necropsy revealed positive immunohistochemical staining for pancreatic

polypeptide and insulin while there was no staining for gastrin, glucagon, or somatostatin. Clinical signs were thought to be due to high plasma PP concentrations since PP decreases pancreatic bicarbonate secretion and mildly increases gastric acid secretion. However, plasma PP may also be elevated in humans with other diseases including inflammatory diseases, renal failure, and laxative abuse; therefore further case reports are needed to characterize this syndrome.

245 CHAPTER • 245 Pheochromocytoma

Elizabeth McNiel

Brian D. Husbands

Pheochromocytoma is a rare tumor that arises from the chromaffin cells of the adrenal medulla. Unlike the steroidogenic cells of the adrenal cortex, which are derived from mesoderm, chromaffin cells are embryologically derived from the neural crest as a part of the sympathetic autonomic nervous system.[1] The adrenal medulla is essentially a modified sympathetic ganglion that lacks postganglionic processes. In the fetus, chromaffin cells are widely distributed and form paraganglia. With the exception of the adrenal medulla, the paraganglia involute at birth.[1] Tumors arising from remnant paraganglia in adult animals are referred to as *paragangliomas* or *extra-adrenal pheochromocytomas*.

245.1 PATHOPHYSIOLOGY

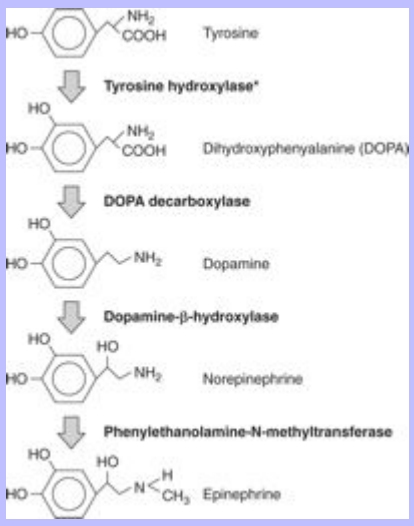
Consistent with the role of the adrenal medulla as a sympathetic ganglion, chromaffin cells are capable of producing, storing, and secreting a variety of neurotrans-mitters and neuropeptides.[2] Catecholamines are the primary secretary product of the adrenal medullary cells, however. Catecholamines, along with other products including ATP and chromagranin, are stored within cytoplasmic vesicles in the chromaffin cells. When the chromaffin cells are stimulated, vesicles are transported to the cell membrane and the contents are expelled via exocytosis.[3]

Catecholamines are synthesized from the amino acid tyrosine through a series of enzyme modifications (Figure 245-1). The first step in catecholamine synthesis involves the conversion of L-tyrosine to L-DOPA through the action of tyrosine hydroxylase. This hydroxylation reaction is the rate limiting step in the pathway and is subject to negative feedback regulation by norepinephrine.[1] In dogs and humans the end product of catecholamine synthesis in the adrenal medulla is predominantly epinephrine, whereas in the cat it is norepinephrine.[4] Pheochromocytomas may produce any of the catecholamines or other physiologically active peptides.

The half-life of catecholamines in circulation is short (minutes). Two enzymes mediate the catabolism: catecholamine-O-methyltransferase (COMT) and monoamine oxidase (MAO).[1,5] The sequential action of COMT and MAO on catecholamines results in the production of the predominant metabolite, vanillylmandelic acid (VMA)[1] (Figure 245-2). Catecholamines and metabolites are excreted in the urine.

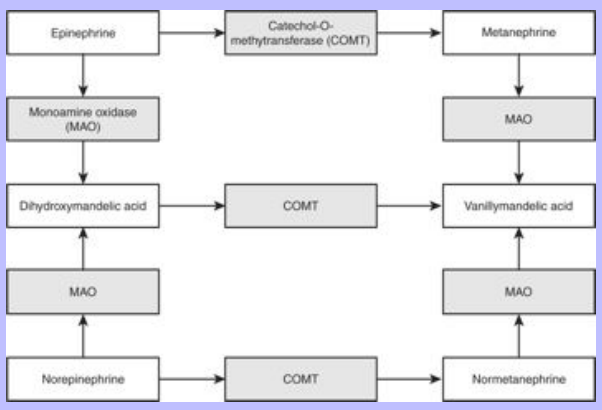
The normal adrenal gland is regulated through a combination of sympathetic innervation and circulating hormones.[2] There is an intricate regulatory connection between the adrenal cortex and medulla. Whereas the peptide products of the adrenal medulla influence steroidogenesis in cortical cells, the steroid hormones influence both differentiation and catecholamine production in the medullary chromaffin cells.[2] One of the hallmarks of neoplastic transformation is the loss of regulatory control, particularly those involved with growth and cell death. For endocrine tumors, such as pheochromocytoma, deregulation may also include loss of normal physiologic control of hormone production and secretion. Thus pheochromocytomas are often associated with increased levels of circulating catecholamines or other physiologically active products.

Figure 245-1 Catecholamine synthesis. *Tyrosine hydroxylase is the rate limiting enzyme and is subject to negative feedback control by norepinephrine.



The action of catecholamines is mediated by specific G protein coupled cell surface receptors[3] (Table 245-1). The receptors are subdivided into α and β types, which include the subtypes αl, α2, β1, β2, and the less prevalent β3. The binding of catecholamines to their receptors initiates cellular increases or decreases in second messengers, which, in turn propagate cellular signaling and affect the cellular response.[3] Epinephrine and norepinephrine have approximately equal affinity for the al, α2, β1 receptors, but epinephrine has higher affinity for β2 receptors.[1,3]

Figure 245-2 Catabolism of catecholamines. *COMT*, catecholamine-O-methyltransferase; *MAO*, monoamine oxidase. Shaded boxes indicate an enzymatic step.



245.2 ETIOLOGY

Cancer is a genetic disease in that inherited and acquired mutations drive the transformation of a normal cell to a tumor cell.[6,7] The cause of genetic mutations in most cancers is not understood and pheochromocytoma is no exception. Roughly 10% of human pheochromocytomas are considered hereditary, the rest, sporadic. Pheochromocytoma may be a feature of a number of distinct hereditary syndromes including multiple endocrine neoplasia type 2 (MEN-2), von Hippel-Lindau disease (VHL), and neurofibromatosis type I[8,9] (Table 245-2). Additional hereditary forms of pheochromocytoma are distinct from these syndromes. Some of the genes that predispose tumor development in the various hereditary disorders have been characterized[8,9] (see Table 245-2). These genes do not appear to play a role in the development of most sporadic pheochromocytoma. A number of chromosomal loci are consistently mutated in sporadic pheochromocytoma, which suggests that these regions contain genes important for pheochromocytoma carcinogenesis.

The role of genetic factors, hereditary or acquired, has not been evaluated in canine or feline pheochromocytoma. Many canine cancers do have a hereditary basis, however. There are reports of dogs with multiple endocrine tumors including a dog with a syndrome similar to MEN-2.[10,11] In addition, a large proportion of dogs diagnosed with pheochromocytoma also have another malignancy, some of these in endocrine tissue. In a search of the Veterinary Medicine Database (VMDB), which contains medical record data abstracted from 26 North American veterinary colleges, the diagnosis of pheochromocytoma was recorded for only 0.05% of canine patients evaluated between 1990 and 2002.

1633

1634

Table • 245-1 The Biochemical Characteristics and Physiologic Effects of Catecholamine Receptors

RECEPTOR TYPE	α1	α2	β1	β2
Biochemistry				
Receptor affinity	Epi ≥ Nor	Epi ≥ Nor	Epi = Nor	Epi >> Nor G_s
G-protein subtype	G_q	G_i	G_s	G_s
Second messenger	↑IP3, DAG	↓cAMP	↑cAMP	↑cAMP
Physiologic Effects				
Ocular	Mydriasis			
Cardiovascular				
Heart			Increase heart rate, contractility, conduction velocity	
Arterioles	Constriction			Dilatation
Veins	Constriction			Dilatation, relaxation
Respiratory				
Bronchial smooth muscle				Relaxation
Gastrointestinal				
Motility	Decrease	Decrease		Decrease
Spincters	Contraction	Contraction		
Liver	Glycogenolysis	Glycogenolysis		Glycogenolysis
Pancreatic acini	Decrease secretion			
Adipose				Lipolysis

ENDOCRINE EFFECTS	ALPHA	BETA
Adrenal cortex	Decreased aldosterone secretion	(Both alpha and beta)
Pancreas		
Alpha cell		Increased glucagon
Beta cell	Decreased insulin	
D cell		Increased somatostatin
PP cell	Increased pancreatic polypeptide	
Gastric antrum		Increased gastrin
Kidney		Increased renin and erythropoietin
Parathyroid		Increased parathyroid hormone
Ovary		Increased progesterone
Testis		Increased testoterone

In the 277 dogs with pheochromocytoma identified in the VMDB, 129 (46%) were diagnosed with other tumors. This finding is consistent with previous reports.[4,12] The presence of multiple tumors in an individual is suggestive of hereditary predisposition.

Fifty-five different breeds were represented among the 277 cases of canine pheochromocytoma in the VMDB. Chi-square analysis comparing the frequency of pheochromocytoma in specific breeds to the frequency of pheochromocytoma in all dogs in the VMDB database revealed significantly increased relative risk of this tumor in seven different breeds of dogs (Table 245-3). Breed predisposition is suggestive of hereditary predisposition, but study of pedigrees is required to confirm this suspicion and to determine the mode of inheritance.

245.3 CLINICAL PRESENTATION

The average age of dogs diagnosed with pheochromocytoma is 10 to 11 years, with a range of 1 to 18 years.[4,12,13] Reports indicate that this is a disease of aged cats. No gender predilection is apparent in either species.[14–16] Although certain breeds may be predisposed to pheochromocytoma, any breed can be affected, including mixed breed dogs.

The clinical signs in dogs with pheochromocytomas are complicated by the high frequency of concurrent illnesses, including hyperadrenocorticism, diabetes mellitus, renal failure, and hepatic disease.[4] In humans with pheochromocytoma, the most common complaints include headache, palpitations, and sweating, which are not readily detectable in dogs and cats. In addition, roughly half of the pheochromocytomas diagnosed in dogs are incidental.

Table • 245-2 Familial and Sporadic Pheochromocytoma in Humans[9,22,32]

CLINICAL CHARACTERISTICS		FREQUENCY OF PEOCHROMOCYTOMA	GENES INVOLVED
MEN-2A	Bilateral medullary thyroid carcinoma; Parathyroid hyperplasia;	20% to 40%	RET
MEN-2B	Bilateral medullary thyroid carcinoma, Phenotypic abnormalities: Bony abnormalities, mucosal neuromas, marfanoid habitus, bumpy lips	60%	RET
VHL	Bilateral renal carcinomas and renal cysts; other tumors	18% to 25%	VHL
NF-1	Cafe-au-lait spots of the skin, Neurofibromas, Hamartomas of the iris, macrocephaly, bone dysplasia, learning disability, seizures, CNS tumors, other malignant tumors such as neurofibrosarcomas and leukemia	1%	NF-1
Sporadic	Older than with hereditary syndromes; Unilateral disease	100%	P53, RB, Others?

MEN, Multiple endocrine neoplasia; *VHL,* von Hippel-Lindau disease; *NF-1,* Nuerofibromatosis type 1, *Sporadic,* Nuerofibromatosis type 1, *Sporadic,* Nonhereditary.

The most common clinical signs in dogs with pheochromocytoma, in the absence of complicating disease, are weakness and collapse.[4] Other historical complaints may be associated with a variety of systems including gastrointestinal (anorexia, weight loss, vomiting, diarrhea), nervous (restlessness, pacing, depression, seizures), cardiopulmonary (exercise intolerance, lethargy), and miscellaneous complaints such as abdominal distension, polyuria, and polydipsia. In cats with pheochromocytoma, polyuria and polydipsia are consistently reported.[14–16]

Clinical signs associated with pheochromocytoma may be related to increased circulating catecholamines or directly associated with the tumor (Table 245-4). Although most pheochromocytomas occur in the adrenal gland, presentation may differ considerably with paraganglioma in extra-adrenal locations, such as the vertebral canal.[17]

Table • 245-3 Relative Risk of Pheochromocytoma in Purebred Dogs Identified in the VMDB Database (1990–2002)

BREED	NUMBER OF DOGS WITH PHEOCHROMOCYTOMA	NUMBER OF DOGS WITHOUT PHEOCHROMOCYTOMA	RELATIVE RISK	95% CONFIDENCE INTERVAL
Airedale terrier	6	1950	5.8	2.6–12.9
Basset hound	5	647	14.4	5.9–34.7
English springer spaniel	8	6639	2.3	1.1–2.5
Golden retriever	31	28,246	2.1	1.5–3.1
Puli	2	130	28.1	7.1–111.8
Weimaraner	5	2167	4.3	1.8–10.4
Wire hair fox terrier	6	1569	7.1	3.2–16.0
Mixed breed	70	109,850	1.2	0.9–1.6
All dogs 1990–2002	277	509,751	NA	NA

245.4 DIAGNOSTIC EVALUATION

245.4.1 Minimum Database

Abnormalities detected in dogs and cats with pheochromocytomas are nonspecific. The presence of concurrent disorders may be reflected in the complete blood count, serum chemistry profile, and urinalysis.[4] Often, the hemogram is normal.[4,13,18] Leukocytosis can be seen secondary to increased circulating catecholamines or stress. Mild anemia may be present secondary to chronic disease or hemorrhage. Thrombocytopenia or thrombocytosis may indicate acute or chronic bleeding, respectively.

Increases in serum liver enzyme activities have been reported in 10% to 25% of pets with pheochromocytoma.[4,13,18] The abnormal serum liver enzyme activities may be secondary to hypertension with changes in hepatic perfusion or can occur with concurrent disease such as hyperadrenocorticism. These abnormal liver enzymes do not correlate with the presence of hepatic metastases.[13]

1635 1636

Table • 245-4 Clinical Signs Associated with Canine Pheochromocytoma[4,12,13,18,33]

EXCESS CATECHOLAMINES	MASS EFFECT
Tachycardia/arrhythmia	Abdominal distention
Polypnea/panting	Weak femoral pulses
Coughing	Hemoabdomen
Ataxia/incoordination	Ascites
Episodic weakness	Pleripheral edema
Seizures	Collapse
Collapse	Budd-Chiari like syndrome*
Blindness (retinal hemorrhages)	
Polyuria/polydipsia	
Anorexia	
Vomiting	
Diarrhea	
Anxiety/pacing	

* Budd-Chiari like syndrome is the mechanical obstruction of the vena cava between the heart and the liver.

Proteinuria, resulting from hypertensive glomerulopathy or concurrent illness, is observed in as many 50% of dogs and cats with pheochromocytomas.[4,13] Hyposthenuria/isosthenuria may be present due to the inhibitory effect of circulating catecholamines on vasopressin secretion and activity.[4]

245.4.2 Blood Pressure

In dogs with pheochromocytoma, the presence of systemic hypertension (systolic pressure >160 mm Hg) is variable (25% to 86% of patients), which may reflect sporadic secretion of catecholamines resulting in intermittent hypertension.[4,13]

245.5 DIAGNOSTIC IMAGING

Imaging techniques are useful for localizing a mass and for determining the extent of disease, including whether the tumor is unilateral or bilateral, is invading local structures, or has metastasized to distant regions.[13] This information is valuable in planning surgical approach and in determining prognosis.

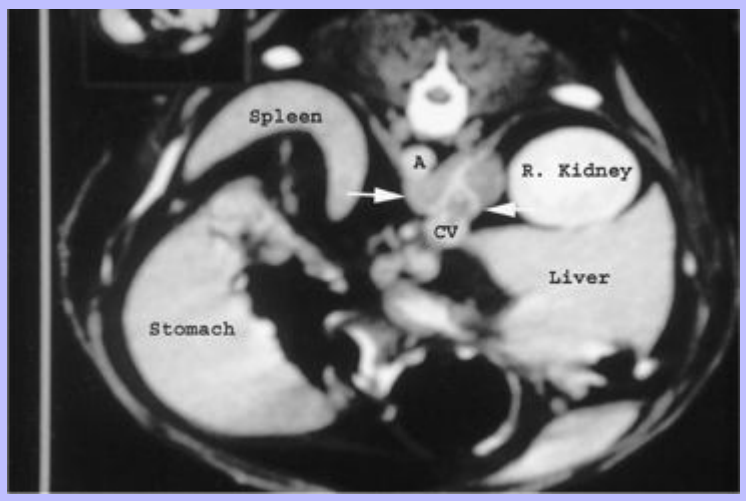
245.5.1 Radiography

Plain abdominal radiographs may reveal a mass or mineralization in the adrenal region.[4,12,13,19] Frequently, the adrenal lesion cannot be detected. Thoracic radiographs may reveal changes consistent with hypertension such as cardiomegaly, pulmonary congestion, or edema.[4,13,18] Contrast studies such as caudal vena cava or nonselective venography and excretory urography may be helpful in detecting caval invasion or thrombosis and renal integrity, respectively.[4,12,13,18,20]

245.5.2 Abdominal Ultrasound

Sonographically, pheochromocytomas appear as mass lesions of the adrenal gland with variable echogenicity.[19,21] Pheochromocytomas cannot be distinguished from other tumors in the adrenal gland based on the sonographic appearance. Other findings could include evidence of metastasis, invasion, or vascular involvement.

Figure 245-3 Transverse abdominal CT image in the cranial lumbar region of a dog with pheochromocytoma. *A*, Aorta; *CV,* caudal vena cava.



245.5.3 Computed Tomography

Computed tomography (CT) is sensitive for lesion localization and in assessment for local invasion and metastasis (Figure 245-3).[4,19] Hypertension secondary to intravenous contrast media (diatrazoate sodium meglumine or iothalamate meglumine) has been reported in humans with pheochromocytomas.[19,22] It is suspected that these medications precipitate catecholamine release. In dogs, hypertension subsequent to administration of contrast media has not been reported.

245.5.4 Magnetic Resonance Imaging

Although there are no reports describing the use of magnetic resonance imaging (MRI) in dogs or cats with a pheochromocytoma, this modality is considered highly sensitive in the detection of pheochromocytoma in humans.[19]

245.5.5 Nuclear Scintigraphy

Scintigraphic studies are used frequently in humans and are reported in the dog for localization of pheochromocytoma.[22–25] Radioactive iodine labeled meta-iodobenzylguanidine (MIBG) is structurally similar to norepinephrine and is taken up by chromaffin cells. This technique is less sensitive than CT for identification of pheochromocytoma in humans but is more specific and it may be useful in the identification of metastases.[25] Octreotide is a somatostatin analog that may be radioactively labeled and binds somatostatin receptors on the surface of neuroendocrine cells such as those in pheochromocytomas. Octreotide scanning may detect lesions in patients with normal MIBG scans.[25]

245.5.6 Positron Emission Tomography

Positron emission tomography (PET) using 6-(^{18}F) fluorodopamine has been helpful in humans when conventional testing is equivocal.[22,26,27] The use of this technique for localization of pheochromocytoma in the dog has been reported and shows promise.[26]

245.6 BIOCHEMICAL DIAGNOSIS

245.6.1 Catecholamine Measurement

Catecholamines, their metabolites, or other neuroendocrine products may be measured in plasma or urine. These techniques are infrequently used in dogs or cats because of limited availability, lack of reference ranges, expense, and complicated sample collection and handling.[4,20,26] In addition, the accuracy of these diagnostics is limited. False-positive results are associated with stress, excitement, certain dietary components, and medications. False-negative results are associated with intermittent secretion of catecholamines by the tumor and improper sample handling.[4,20,26]

245.6.2 Provocative Testing

Certain agents, including histamine, tyramine, metoclopromide, and glucagon, cause adrenal catecholamine release and can be used to screen individuals for pheochromocytoma.[4,20] Because of the risk of a hypertensive crisis, these tests are not recommended.

245.6.3 Clonidine Suppression Test

Clonidine is a centrally acting α-agonist that suppresses the release of catecholamines. In all patients, blood pressure and heart rate can decrease after administration. Lack of reduction in plasma catecholamines following administration of clonidine is consistent with pheochromocytoma.

245.6.4 Phentolamine Test

Phentolamine is an α-receptor antagonist, thus administration inhibits α-mediated vasoconstriction. In patients that are hypertensive secondary to excessive catecholamines, phentolamine results in vasodilation and decreased blood pressure within minutes of administration, an effect that lasts about 10 minutes. This test is not recommended due to potential for hypovolemic shock and difficulties in interpretation.

245.7 PATHOLOGY

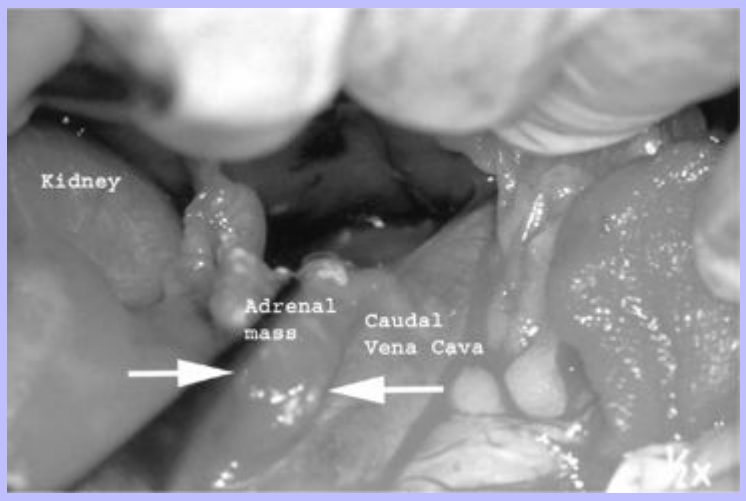
245.7.1 Cytology

Although there is some potential to induce a hypertensive crisis or hemorrhage, fine-needle aspiration can be performed with ultrasound or CT guidance. Cytologic features of pheochromocytoma are consistent with a tumor of neuroendocrine origin. Cytologic misdiagnosis has been documented.[13]

245.7.2 Histopathology

Microscopically, pheochromocytomas are composed of nests of polyhedral cells with lightly eosinophilic, granular cytoplasm that are separated by a fine fibrovascular stroma.[13,23,28] Immunohistochemical techniques may be useful in distinguishing pheochromocytoma from other tumors of the adrenal gland.[4,28] The distinction between benign and malignant tumors is unclear. In humans, presence of capsular or vascular invasion and nuclear pleomorphism do not correlate with behavior.[23]

Figure 245-4 Intraoperative photograph demonstrating a noninvasive pheochromocytoma in a dog.



245.8 TREATMENT

245.8.1 Surgery and Perioperative Management

Surgical excision of pheochromocytoma is the treatment of choice (Figure 245-4). Surgical and anesthetic complications are common, however. The surgical approach to adrenalectomy has been described.[29]

Pre-anesthetic goals include stabilization of hypertension and control of arrhythmias.[30] Treatment with α-receptor antagonists, such as phenoxybenzamine or prazosin, will normalize intravascular volume in individuals with chronic hypertension. Arrhythmias should be treated with β-adrenergic antagonists such as propanolol or esmolol. It may be prudent to normalize blood pressure and rhythm disturbances for 1 to 2 weeks prior to surgery in light of the high complication rate reported in dogs and cats.[18,30,31]

Medications that stimulate release of catecholamines or may precipitate arrhythmias (ketamine, morphine, and halothane) should be avoided. Anesthetic protocols used in humans include the use of thiopental, propofol, isoflurane, or sevoflurane.[30]

Careful monitoring of blood pressure, cardiac rhythm, and red cell volume is essential. Manipulation of a pheochromocytoma can induce catecholamine release with subsequent hypertension. Following resection, hypovolemia may occur as the circulating catecholamine concentrations decrease. Hypotension is best managed by administration of intravenous crystalloids. In dogs that have a poor response to fluid expansion, dopamine may be indicated. Postoperatively, monitoring must continue until the animal is stabilized. In one study of dogs undergoing surgical resection of pheochromocytoma, hospitalization time ranged from 3 to 12 days.[31]

245.8.2 Medical Management

Dogs or cats with nonresectable or metastatic pheochromocytoma may be treated medically. The goals of medical therapy are to control sequelae to elevated catecholamines (hypertension and arrhythmias) and control of the tumor (both primary and metastatic).

245.8.3 Chemotherapy

Chemotherapy has not been evaluated for treatment of pheochromocytoma in dogs or cats. Humans with malignant pheochromocytoma are often treated with protocols combining vincristine, cyclophosphamide, and dacarbazine, which prolongs survival in patients with metastatic disease.[23] In addition to typical chemotherapy related side effects, there is some risk of inducing a hypertensive crisis due to tumor cell lysis with release of stored catecholamines.[23]

245.8.4 Targeted Therapy

Radiolabeled MIBG, in addition to imaging applications, has demonstrated efficacy in the treatment of malignant pheochromocytoma in humans either alone or in combination with chemotherapy. Similarly, octreotide may be useful in people if octreotide scintigraphy demonstrates uptake. Neither of these techniques has been reported in the dog.

245.9 PROGNOSIS

Animals with surgically resectable pheochromocytoma can have prolonged survival times. The median survival time for six dogs with surgical resection was 15 months. For dogs surviving the immediate postoperative period, a range in survival from 2 to 40 months has been reported.[4] Prognosis in cats is probably similar. In the few reported cases of pheochromocytoma in cats, only one cat survived postoperatively. Metastasis has been reported in 13% to 50% of dogs with pheochromocytoma. Sites of metastasis include liver, regional lymph nodes, spleen, lungs, brain, and bone (femur and lumbar vertebral body). Metastasis of feline pheochromocytoma has not been reported.

246 CHAPTER • 246 Estrous Cycle and Breeding Management of the Healthy Bitch

Auke C. Schaeferes-Okkens

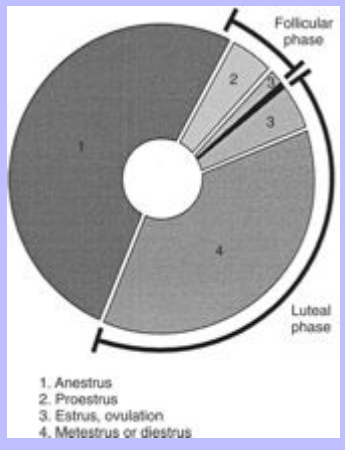
246.1 THE ESTROUS CYCLE

Onset of puberty in the healthy bitch occurs between 6 and 18 months of age. After each estrous cycle, which has a length of about 3 months, an anestrus with a variable duration occurs. The mean interval from onset of one estrous cycle to the next is about 7 months, with a range of 4 to 12 months. The interestrous interval may be regular or variable within individual bitches. After 8 years of age, the duration and frequency of the cycles become less regular and the interestrous interval increases.[1]

The stages of the estrous cycle are proestrus, estrus, and diestrus (metestrus) (Figure 246-1). The average duration of proestrus is 9 days, with a range of 3 to 17 days. Proestrus is defined as the period when the bitch is sexually attractive while rejecting the male's advances until the first willingness to accept the male. However, early behavioral signs are indistinct. Therefore it is common to use the onset of serosanguineous vaginal discharge and vulvar swelling to mark the first day of proestrus.

On average, estrus (the period of acceptance of the male) has a duration of 9 days, with a range of 3 to 21 days. During estrus the vulva begins to shrink and soften. The discharge usually persists, but generally diminishes. It may remain serosanguineous or turn straw-colored. Diestrus begins when the bitch will no longer accept the dog. It has an average duration of about 70 days if it is assumed to end when the plasma progesterone concentration initially declines to a level of less than or equal to 3 nmol/L (lnmol/L =0.315 ng/ml). In addition to this behavior-oriented classification of the cycle, it is also possible, and more appropriate, to concentrate on ovarian function and to classify the follicular phase, the phase of preovulatory luteinization and ovulation, the luteal phase and the anestrus (see Figure 246-1).

Figure 246-1 Diagram of the estrous cycle and anestrus in the dog. (From Schaefers-Okkens AC: The ovaries. In Rijnberk A: *Clinical endocrinology of dogs and cats*. Netherlands, 1996, Kluwer Academic Publishers.)



246.2 FOLLICULAR PHASE

As tertiary follicles develop in the ovaries they produce estradiol, leading to peak plasma levels of 180 to 370 pmol/l in late proestrus, 1 to 2 days before the preovulatory luteinizing hormone (LH) surge (Figure 246-2). On laparoscopic inspection, follicle development is not readily apparent on the ovary because of the ovarian bursa. Furthermore, until mid-proestrus, follicular development appears only as clear grayish areas with indistinct boundaries on the ovarian surface. These areas gradually develop into distinct fluid-filled vesicular follicles, which protrude distinctly above the ovarian surface.[2] The external signs of proestrus, such as hyperemia and edema of the vulva and bloody vaginal discharge, are caused by increased concentrations of estradiol (Figure 246-3). This also causes lengthening and hyperemia of the uterine horns, enlargement of the cervix (which can be palpated), and thickening of the vaginal wall.

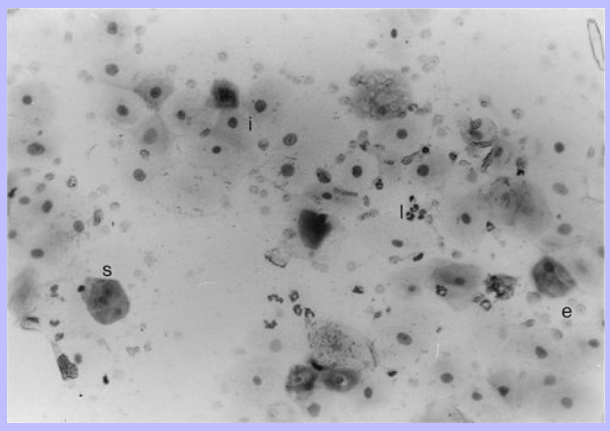
The percentage of superficial cells in the vaginal smear increases and the percentage of parabasal and small intermediate cells decreases. Erythrocytes are numerous, and leukocytes are seen in the early follicular phase but disappear as cornification progresses (Figure 246-4). Superficial cells dominate as the follicular phase progresses (Figure 246-5). However, it should be realized that although vaginal cytology gives an indication of the stage of the cycle, it is not reliable for timing the preovulatory LH surge or ovulation.[3]

Figure 246-4 Vaginal cytology in the bitch at the onset of the follicular phase, showing primarily intermediate *(i)* cells, some superficial *(s)* cells, erythrocytes *(e)*, and leukocytes *(l)* (May Grünwald Giemsa, original magnification, 200).

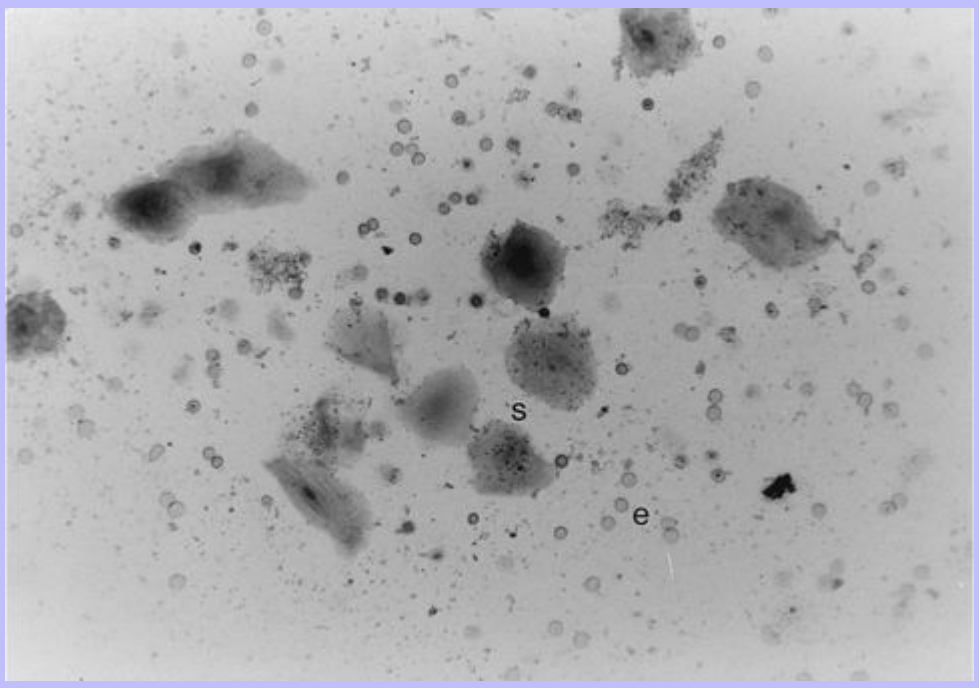


With vaginoscopy it can be observed that the vaginal mucosal folds are swollen, are pale, and have smooth, rounded surfaces (balloons) (Figure 246-6). The increased concentrations of estradiol frequently cause hypertrophy of the floor of the posterior vagina, just cranial to the urethral orifice and therefore folding over and covering the urethral orifice (Figure 246-7). At the end of the follicular phase that is during the decline in estradiol and the rise in progesterone concentrations in plasma, shrinkage begins in response to reduced estradiol-dependent water retention. These cyclic changes are most marked in the dorsal median fold and precede those of the mid-vaginal mucosa (Figure 246-8).

1641

1642

Figure 246-5 Vaginal cytology in the bitch during the second half of the follicular phase, at ovulation, and the onset of the luteal phase. This smear shows superficial cells (s) and erythrocytes (*e*). (May Grünwald Giemsa, original magnification 200)



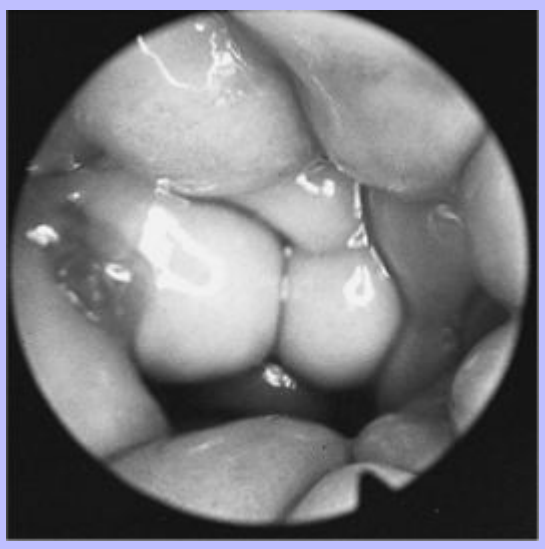
The basal plasma follicle-stimulating hormone (FSH) concentration is relatively low during the follicular phase, whereas the basal plasma LH concentration is higher than in different phases of the anestrus (Figure 246-9). The secretory pattern of LH is characterized by frequent increases of short duration.[4] Plasma progesterone concentrations initially remain low but fluctuate and increase during the second half of the follicular phase as a result of partial luteinization of the follicles.

246.3 PRE-OVULATORY LUTEINIZATION AND OVULATION

The pre-ovulatory surge of LH lasts 24 to 72 hours. It usually starts shortly after the estradiol peak and coincides with declining estradiol and rising progesterone concentrations in plasma (see Figure 246-2). Rapid and extensive

luteinization takes place during the preovulatory LH surge. Ovulating follicles therefore have many of the characteristics of rapidly developing corpora lutea. Most ova in the dog are ovulated in an immature state as primary oocytes. The process of ovulation can take up to 24 hours. In the first 2 to 3 days after ovulation the oocytes mature; that is, they undergo the first meiotic division and the extrusion of the first polar body, after which fertilization can occur.[5]

Figure 246-6 Vaginoscopy in the bitch at the onset of the follicular phase. Note the swollen, pale mucosal folds with smooth rounded surfaces (balloons) and the bloody secretion between the folds.



Plasma progesterone levels are 6 to 13 nmol/L at the time of the LH peak, and 15 to 25 nmol/L at the time of ovulation, 36 to 48 hours later. Concurrent with the LH peak, a pre-ovulatory surge in FSH occurs that reaches peak concentrations 1 to 2 days after the LH peak. Estrus behavior usually starts synchronously with the pre-ovulatory LH peak (see Figure 246-2), but some bitches initially demonstrate estrus behavior days before or after the LH peak.[6] Shrinkage of the vaginal mucosa starts about midway in the follicular phase and continues through the phase of pre-ovulatory luteinization and ovulation, when many longitudinal folds can be observed (Figure 246-10). 1642 1644

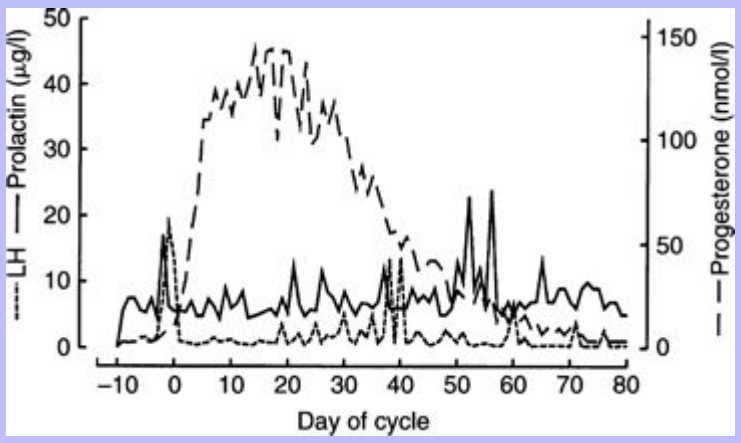
246.4 LUTEAL PHASE

Plasma concentrations of progesterone originating from the corpora lutea increase during the remainder of the estrus and during the onset of diestrus. Estrus behavior is thus seen during the period of a rising plasma progesterone concentration. Increased progesterone concentrations plateau at 10 to 30 days after the LH peak. Thereafter, in non-pregnant bitches, the progesterone secretion declines slowly and reaches a basal level of 3 nmol/l for the first time at about 75 days after the start of the luteal phase (Figure 246-11).

During the initial part of the luteal phase, the transition from estrus to diestrus takes place. In this period, the cytology of the vaginal mucosa changes from primarily superficial cells to mainly intermediate and parabasal cells and leukocytes (Figure 246-12). This change is an indication that the fertile period has expired. During oocyte maturation, shrinkage of the vaginal mucosa continues and increasing numbers of sharp edged summit profiles appear. In the transition period from estrus to diestrus, the mucosa thins and profiles become round. At the start of diestrus, a patchwork of red and white areas can be seen (Figure 246-13).

Figure 246-11 Mean LH, progesterone, and prolactin levels in plasma of three dogs during the follicular and luteal phase. The data have been synchronized on day 1, the day after the onset of the follicular phase on which the progesterone concentration in the peripheral blood had reached 16 nmol/l. (From Schaefers-Okkens AC: The ovaries. In Rijnberk A: *Clinical endocrinology of dogs and cats,* Netherlands, 1996, Kluwer Academic Publishers.)



The factors that are responsible for initiating the regression of the corpora lutea in the dog are still unknown. Prostaglandin $F_{2\alpha}$ originating from the endometrium is not the causative factor in the bitch as it is in the cow and sheep. This is demonstrated by the fact that hysterectomy does not influence the length of the luteal phase.[7]

Prolactin acts as a luteotropic factor in the second half of the luteal phase.[8,9] During the first half of the luteal phase the corpus luteum functions independent of pituitary support.[10] Thereafter, inhibition of prolactin secretion causes a sharp decrease in progesterone secretion (Figure 246-14). LH concentrations change little during the luteal phase, with the exception of a slight increase in the second half of the luteal phase (see Figure 246-11). There is no proof of direct luteotropic properties for LH in the cyclic bitch.[9,11]

Pseudopregnancy is a syndrome that in greater or lesser degree accompanies the extended luteal phase of all non-pregnant ovarian cycles in the bitch. If the nature of the syndrome is mild, it is generally referred to as a *physiologic* or *covert pseudopregnancy*. In contrast, overt or "clinical" pseudopregnancy includes obvious mammary development, changes that are not distinguishable from the changes of late pregnancy, or lactation are seen (see Chapter 247). Mammary gland development is influenced by prolactin and growth hormone (GH) and their secretion pattern is influenced by progesterone.[12] GH, produced in the mammary gland itself, may promote the physiologic proliferation and differentiation of mammary gland tissue during the luteal phase by local autocrine/paracrine effects, prolactin is important for lobuloalveolar development.[13]

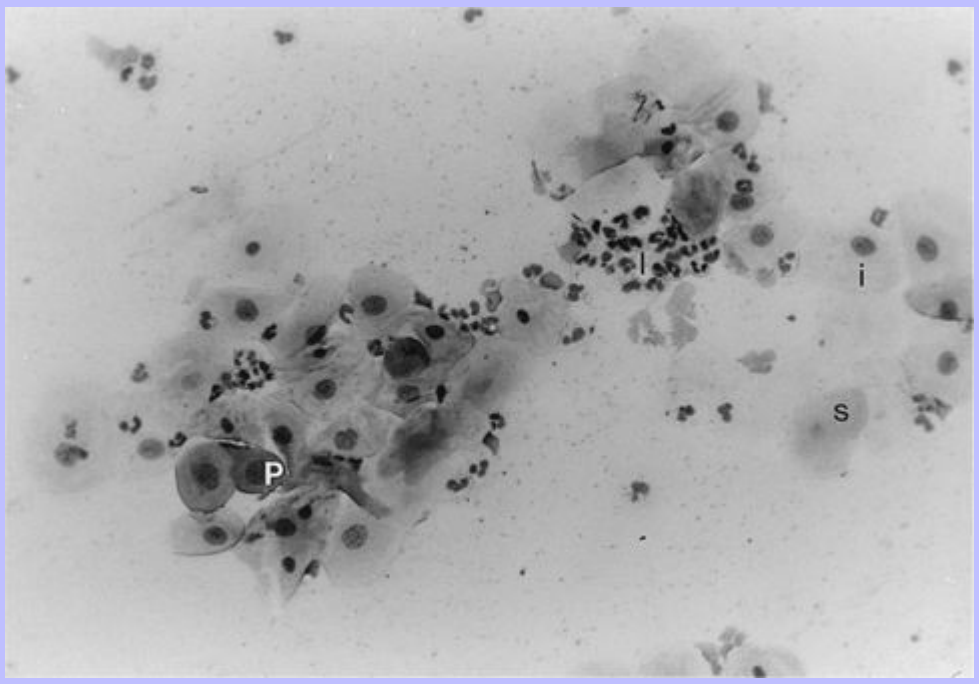
In the start of the luteal phase, a higher basal GH secretion is present, with less GH being secreted in pulses than during the last part of the luteal phase, where the basal GH secretion is lower with more GH being secreted in

pulses. This phenomenon may be explained by partial suppression of pituitary GH release by progesterone-induced GH production in the mammary gland (Figure 246-15).[12] In most non-pregnant bitches the decline in plasma progesterone concentrations during the luteal phase is associated with a moderate but significant increase in prolactin secretion (see Figures 246-11 and 246-15).[12] In the overt pseudopregnant bitch, however, the plasma prolactin concentration may strongly increase, probably corresponding with the degree of "clinical" pseudopregnancy.[14]

1644

1645

Figure 246-12 Vaginal cytology during diestrus, which starts 6 to 10 days after the preovulatory LH peak. This smear shows intermediate cells *(i)*, parabasal *(p)* cells, and leukocytes *(l)* (May Grünwald Giemsa original magnification, 200).

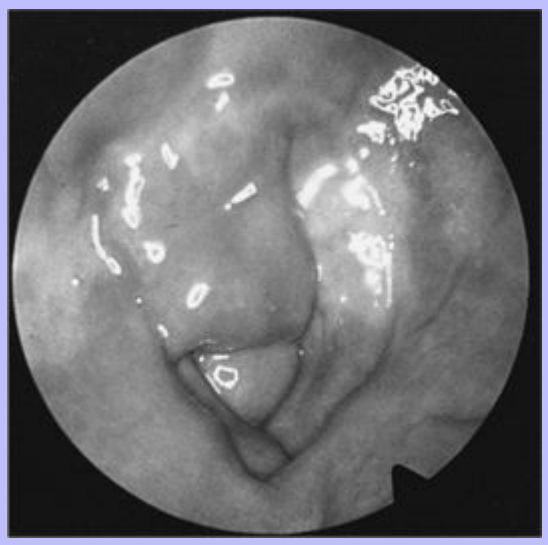


246.5 ANESTRUS

The time of the onset of anestrus depends on which criteria are being used to define the end of the luteal phase: for example, after 2 to 3 months when mammary development subsides, the first time that the plasma progesterone concentration reaches a level below 3 nmol/L, or the moment that the influence of progesterone on the endometrium is no longer evident. In any case, the transition from the luteal phase into anestrus is gradual and varies considerably among bitches. The transition from anestrus to follicular phase can begin at any time throughout the year and there appears to be little, if any, seasonal influence. Breed differences and strains within breeds can form the basis of variation in mean interestrous intervals. In the Collie, for instance, the mean interval is 36 weeks, and in the Alsatian, it is about 20 to 22 weeks. Some breeds such as the Basenji and Tibetan Mastiff, however, have a single annual estrous cycle, which may possibly be influenced by a photoperiod. Environmental factors can also affect the interestrous interval: an anestrous bitch placed in close proximity to a bitch in estrus

can show an advance of the onset of proestrus by several weeks. Furthermore, bitches housed together often have synchronous estrous cycles.

Figure 246-13 Vaginoscopy during diestrus. Note the rounded profiles and the patchwork of red and white areas.

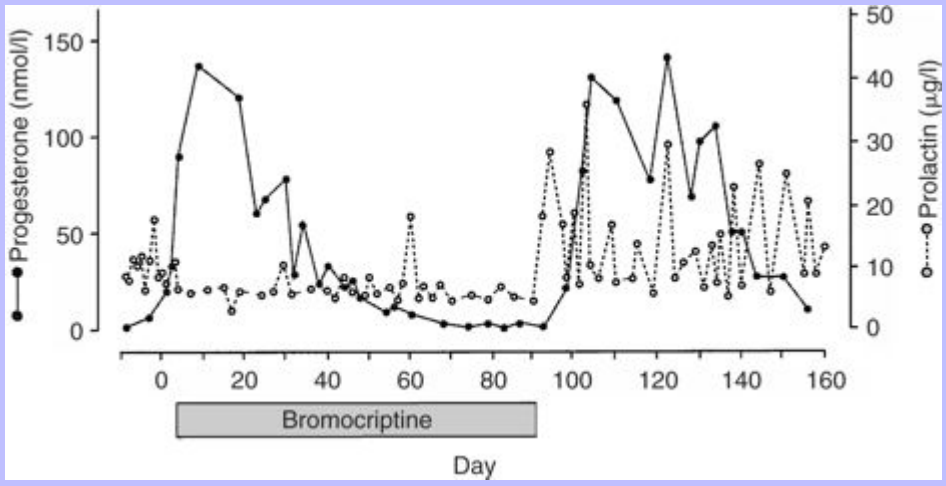


Progression from early to late anestrus is characterized by a greater amplitude and a higher number of GnRH pulses by the hypothalamus, an increase in the sensitivity of the pituitary to GnRH from early to late anestrus, and an increase in ovarian responsiveness to gonadotropins.[15,16] Furthermore, the increase in the basal plasma FSH concentration should be considered to be a critical event required for the initiation of folliculogenesis (see Figure 246-9).[4,17] In addition, a period of increased LH pulsatility is observed shortly before the onset of proestrus.[4,18,19] There is some evidence that factors that decrease opiodergic activity promote LH release and the termination of anestrus.[18] Finally, during the course of anestrus in the bitch, there is an increase in hypothalamic mRNA encoding for the estrogen receptor and the expression of the gene for P450 aromatase, which catalyzes estrogen biosynthesis.[20,21] Although sporadic elevations are observed, plasma estradiol concentrations are usually low and do not begin to rise until late anestrus.

Apart from these changes in the hypothalamic-pituitary-ovarian axis, there is an involvement of dopaminergic influences in the initiation of a new follicular phase in the bitch. Administration of the dopamine agonists bromocriptine and cabergoline shortens the anestrus and is associated with a decrease in the plasma prolactin concentration, which suggests that the shortened anestrus is the result of the suppression of prolactin secretion.[8,22] However, the anestrus of dogs treated with metergoline, a drug that in a low dose lowers the plasma prolactin concentration via a serotonine-antagonistic pathway, is not shortened, which indicates that not the decrease in the plasma prolactin concentration, but the dopamine-agonistic influence is a critical event in the transition to a new follicular phase.[23] Furthermore, a low dose of bromocriptine, which does not decrease the plasma prolactin concentration, prematurely induces a new follicular phase.[24] In addition, under physiologic conditions low plasma prolactin concentrations are found during anestrus and no obvious changes in the plasma

prolactin concentration have been observed in the bitch during the transition from anestrus to the follicular phase (see Figure 246-15).[4,25]

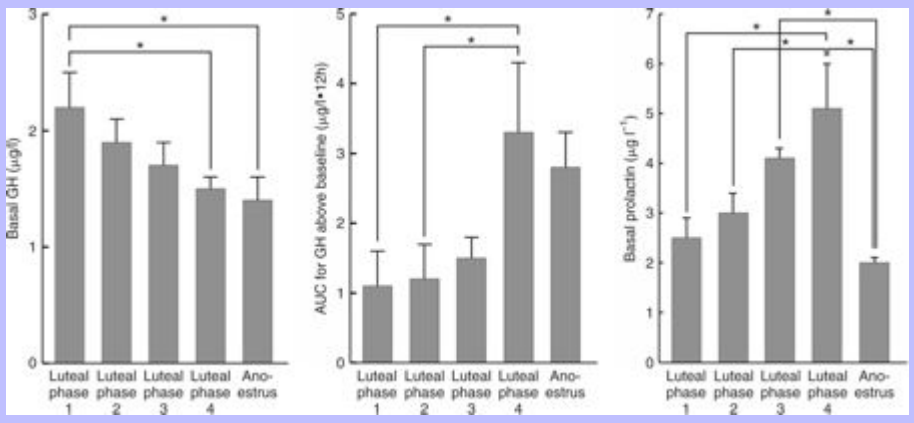
Figure 246-14 Progesterone and prolactin levels in the peripheral blood of one dog, treated with bromocriptine (bar) from ovulation in the first cycle until the onset of the next follicular phase. The luteal phase and especially the anestrus are considerably shortened. (From Schaefers-Okkens AC: The ovaries. In Rijnberk A: *Clinical endocrinology of dogs and cats,* Netherlands, 1996, Kluwer Academic Publishers.)



Bromocriptine-induced shortening of the anestrus is associated with a quick rise in the basal plasma FSH concentration without a concomitant increase in the basal plasma LH concentration[26], similar to what is observed during the physiologic late anestrus. This again indicates that in the bitch an increase in the circulating plasma FSH concentration is a critical event in the initiation of ovarian folliculogenesis.[4]

As a consequence of what is described, induction of a follicular phase may take place by pulsatile administration of GnRH. In a study, in which GnRH was administered in pulses of 15 to 500 ng/kg every 90 minutes for 7 to 9 days to 36 anestrous bitches, GnRH pulses resulted in proestrus, estrus, ovulation, and pregnancy in 26, 20, 16, and 12 bitches, respectively. Efficacy was dose dependent.[27] A fertile estrus could also be induced by administering a timed-release GnRH agonist, followed by a GnRH analogue on the first day of induced estrus.[28] Anestrus can also be terminated by treating bitches with porcine LH. In one study proestrus was induced in all bitches (n =16). Twelve bitches came in estrus, from which seven ovulated. Bitches, in which proestrus but not estrus occurred, were all treated in early anestrus.[29] The observed rapid increase of plasma estradiol concentration after LH treatment suggests that increased follicle steroidogenesis is a primary effect of LH. On the other hand the insufficient reaction to porcine LH of bitches in early anestrus may be due to a deficiency of FSH or FSH receptors in this stage of anestrus. Follicular aromatase in rats and most other species studied appears to be primarily under up-regulation control by FSH.[30]

Figure 246-15 The mean (± SEM) basal plasma GH concentration, the mean (± SEM) area under the curve (AUC) for GH above the baseline and the mean (± SEM) basal plasma prolactin concentration in six beagle bitches. Blood samples were collected at 10-minute intervals for 12 hours at four stages of the luteal phase (luteal stage 1 through 4, with mean plasma progesterone concentrations of 123, 56, 20, and 9 nmol/L, respectively) and during mid-anestrus. *Indicates statistically significant difference. (Modified from Kooistra HS, Okkens AC: Secretion of growth hormone and prolactin during progression of the luteal phase in healthy dogs: a review, *Mol Cell Endocrinol* 197:167, 2002.)



Anestrus can thus also be shortened considerably by administration of dopamine-agonists such as bromocriptine and cabergoline.[8,18,22,31] When bromocriptine treatment, twice daily 20 µg/kg, orally, is started during the luteal phase, the interestrous interval can be shortened from 245 days to 100 days (see Figure 246-14).[8] When started during the anestrus 100 days after the ovulation the next proestrus can be expected after a mean period of about 45 days.[31] The fertility of an estrus initiated by bromocriptine treatment appears to be normal.

1646

1647

246.6 BREEDING MANAGEMENT OF THE HEALTHY BITCH

Breeding management starts with the determination if the bitch is healthy and if a normal fertility can be expected (Figure 246-16). For that reason the age and the breeding history of both the bitch and the male dog have to be considered. Thereafter, a complete gynecologic examination of the bitch is needed. Recurring examinations should be performed during the follicular phase, ovulation, and pregnancy. A decrease in fertility may be expected with increasing age. One of the reasons for this diminished fertility may be the development of cystic endometrial hyperplasia (CEH; see Chapter 251).

246.7 THE HISTORY CONCERNING THE REPRODUCTION DATA

The reproduction history of the bitch must be considered in the breeding management program. The age of the bitch at her first estrus and the length of the interestrous intervals are important. The bitch that has not experienced an estrus by 18 months of age is considered to have a primary anestrus. One of the major causes of primary anestrus is probably true hermaphroditism or pseudohermaphroditism. If a bitch has experienced estrus, an interval of more than 12 months or an interval that is double the usual interestrous interval for that individual bitch is considered to be a prolonged interestrous interval.

One reason for a prolonged anestrus can be hypothyroidism. However, it should be realized that less pronounced cases of hypothyroidism may result in prolonged or abbreviated proestrus or weak estrus symptoms instead of anestrus. Anestrus may also be induced with drugs such as progestagens or glucocorticosteroids. Glucocorticoids probably decrease levels of circulating gonadotropic hormones.[32] In bitches older than 8 years of age, the duration and frequency of the cycles become more irregular and the interestrous interval increases. An apparent prolonged anestrus can be present if the bitch has a silent estrus or if the owner did not observe the estrus properly. Shortened interestrous intervals (intervals of less than 4 months) may be caused by a split heat or are seen in combination with persistent estrus (see Chapter 247).

Attention must also be given to the length of estrous periods. The average length of proestrus and of estrus is 9 days each. The bitch is considered to have a persistent estrus, if ovulation has not occurred after about 25 days from the onset of proestrus. In that case the plasma progesterone concentration will be lower than 16 nmol/L, and estrus symptoms such as sanguineous discharge, estrus behavior, estradiol influence seen during vaginoscopy, and/or the presence of superficial cells in the vaginal smear are present. Plasma estradiol concentrations are not consistently elevated.[33] Persistent estrus can be caused by ovarian tumors and cysts (see Chapter 247).

Attention must also be given to attempts to mate the bitch and/or the results of matings in previous cycles, previous pregnancies and parturitions and how many puppies were born. There are a number of problems that can lead to an unsuccessful mating. One problem can be inexperience or behavioral problems from bitch and/or male dog. Also anatomic disorders may prevent a normal mating. Strictures, adhesions, septa, and hyperplasia, for example, are common in bitches.[34] They can be congenital or acquired as a result of local treatment of vaginitis with irritating drugs (see Chapter 253).

Another important reason for a failure to mate or a missed conception is mating at an improper moment. A large number of fertility problems are the result of inappropriate management of the bitch and are avoidable if a proper breeding program is used. Additionally, CEH or CEH-endometritis or infectious diseases such as canine brucellosis or herpesvirus infection may also lead to breeding problems. Infertility due to CEH without endometritis, in which case the bitch does not show signs of a systemic disease, may be diagnosed during an ultrasonographic examination.

Canine brucellosis is a contagious disease for which the clinical manifestations vary greatly. It is characterized in the bitch by generalized lymphadenopathy and by early embryonic death, abortion (mainly between the 45^{th} and 55^{th} day of gestation), and infertility.[35] Canine brucellosis must be considered whenever there is a history of abortion or poor reproductive performance in either sex. The diagnosis can, however, not be established based on clinical signs alone. Serologic tests are necessary to confirm the diagnosis of canine brucellosis.

Canine herpesvirus can cause a high percentage of dead puppies in the first weeks after parturition. Herpesvirus does not seem to lead to a decrease in fertility.

246.8 THE EXAMINATION OF THE BITCH

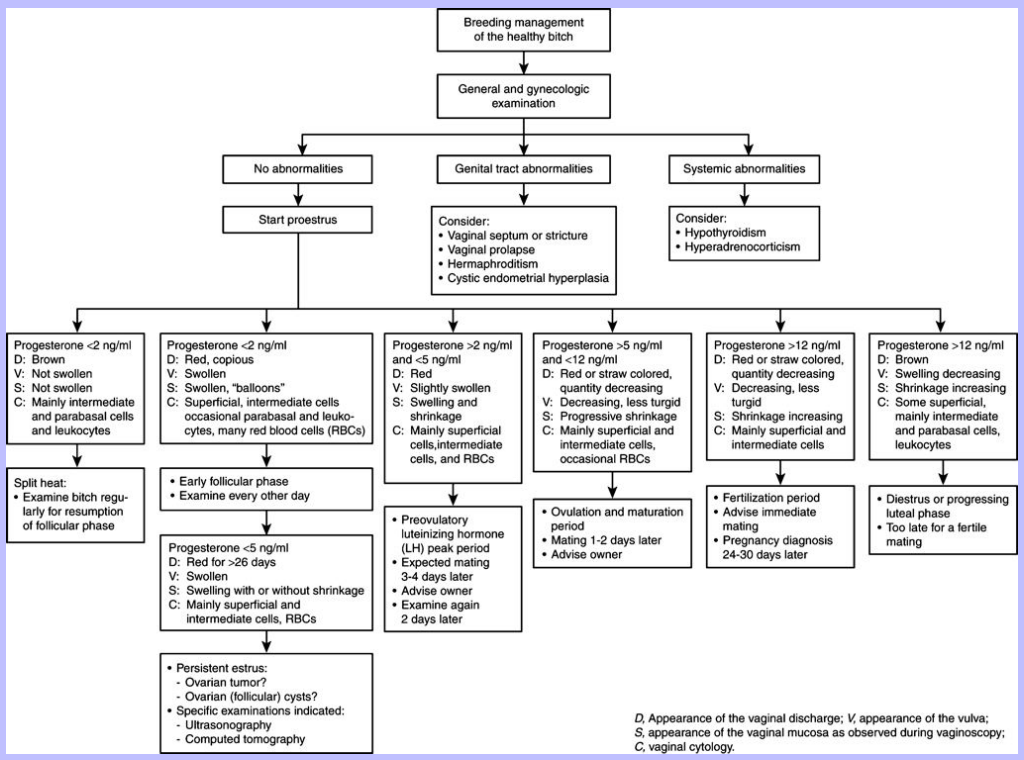
Breeding management starts with a general examination followed by sequential examinations. During the gynecologic portion of the first examination special emphasis should be given to palpation of the uterus and digital evaluation of the vagina. The following items should be examined every other day, starting 5 to 6 days after onset of proestrus: the vulva (size, swelling), vaginal discharge (quantity, color), and vaginoscopic, and cytologic findings. Furthermore, the owner should be asked to look for behavioral changes consistent with estrus. The start of estrus behavior usually occurs synchronously with the preovulatory LH peak (see Figure 246-2), but the first signs of this behavior can be observed several days before or after the LH peak or may never be seen. Repeated examinations are carried out to determine if the cycle is progressing normally (see Figure 246-16).

Vaginoscopic and cytologic observations not in agreement with the expected stage of the cycle may be a sign of a fertility disorder, which may or may not be serious. For example, a split heat is common in both younger and older healthy bitches. In cases of split heat, the follicular phase stops before ovulation and resumes after a few days or weeks. The vaginal discharge changes from red to brown; the smear shows intermediate cells, parabasal cells, and leukocytes and the swelling of the vaginal mucosal folds diminishes. It is probably caused by prematurely regressing follicles. Ovulation will generally occur if proestrus returns. Treatment is usually not necessary, but close monitoring of the cycle is essential for determining the appropriate mating period.

Sequential examinations should also be carried out to determine the ovulation period. Data concerning vulvar swelling, vaginal discharge, and vaginoscopic and cytologic findings have been described. Because of the variable length of proestrus and estrus, it should be clear that breeding a bitch on preset days of the cycle (e.g., 11 to 13 days after onset of proestrus bleeding) gives inconsistent results. Although breeding in accordance with estrus behavior will give better results, some bitches are nevertheless bred too early and others too late. Determination of the ovulation period is therefore of value. Several methods have been described to determine the ovulation period and the proper period for mating. The principal methods are measurement of the plasma progesterone concentration and vaginoscopy.

Plasma progesterone concentrations should, along with the other examinations, be determined every other day. 1647
At the onset of the follicular phase, determined through cytologic and vaginoscopic findings, the time between 1649
two determinations of plasma progesterone may be longer than in the progressing follicular phase. Use of an enzyme-linked immunosorbent assay (ELISA) or enzyme immunoassay kit for plasma progesterone determination may be less accurate, especially in medium (progesterone: >3 nmol/L, <16 nmol/L) plasma progesterone concentrations as compared with a plasma progesterone determination via a radioimmunoassay (RIA).[36,37] The RIA method is therefore the preferred method for progesterone determination. When frozen or chilled extended semen is being used, and sperm life span is expected to be shorter than in fresh semen, it is especially advisable to determine plasma progesterone concentrations by RIA to ensure accuracy in determining the ovulation day and the fertile period, therefore permitting use of a single insemination.

Figure 246-16 Algorithm for the breeding management of the healthy bitch.



Plasma progesterone concentrations increase slightly at the time of the preovulatory LH peak and rapidly at the onset of ovulation. At this time the plasma progesterone concentration exceeds 16 nmol/L. The onset of the optimal period for mating is 24 hours later and is based on the time needed for maturation of the oocytes, capacitation, and life span of the sperm.[38] With determination of the period for mating using a rapid RIA for the plasma progesterone concentration, it was found that 105 of 112 (94%) bitches with normal fertility became pregnant and 81 of 104 bitches (78%) with suboptimal fertility became pregnant. In the latter group, only 23% of previous matings without proper breeding management had been successful.[39]

Determination of the preovulatory LH peak would also provide an excellent parameter for the estimation of the ovulation time. In-hospital ELISA LH kits are available. However, more frequent blood sampling is required than for progesterone because of the risk of missing the preovulatory LH peak. Vaginoscopy can also be used to try to establish the ovulation period. The mucosal changes are, however, a response to hormonal changes and are therefore secondary changes. Additionally, interpretation of the changes is subjective.

Vaginoscopy is thus a less reliable method of estimation of the ovulation period than measurement of hormone levels. For experienced veterinarians, it can be a useful tool for monitoring the stage of the cycle, but mating advice based on vaginoscopy should include the recommendation to mate at least twice, with an interval of 48 hours. Vaginal cytology is useful in diagnosis of early proestrus, progressing proestrus-estrus, or diestrus. There are, however, no reliable changes in the smear indicative of the preovulatory LH surge or of ovulation.[3] Lastly, ultrasonography is not reliable for ovulation determination.[40]

246.9 ADDITIONAL EXAMINATIONS

In bitches with previous fertility problems, vaginal culture may be of use. A mixed bacterial flora, including *Pasteurella,* beta-hemolytic streptococci, and *Escherichia coli,* often inhabits the canine vagina and should not be considered a causative factor for infertility. In an examination of the aerobic bacterial flora of the genital tract of 59 bitches in four breeds during different stages of the cycle and pregnancy (all bitches whelped at least once during this study), culture results were negative in only 5%. Although the cultures in general showed a mixed flora, single species were obtained from 18% of the specimens. The aerobic bacterial flora consisted of common opportunistic pathogens.[41] Therefore bacterial culturing of vaginal swab specimens from bitches without signs of genital disease is of little value. Treatment is indicated in cases of suspected genital inflammation only if there are many bacteria (more than 100 colonies per culture) or the culture reveals only one species. Treatment may be systemic or local, but locally applied drugs alter the vaginal environment, are often spermicidal, and should therefore not be used shortly before breeding.

Pregnancy diagnosis is important within a breeding management program. Between 26 and 32 days after mating, pregnancy may be diagnosed by abdominal palpation. In some bitches an earlier diagnosis can be made depending on the degree of muscular guarding, thickness, and breed. The examination should, however, be repeated in case of a negative finding. In case of a negative or dubious finding, if vesicles of different size and elasticity are palpated, or if only one or two gestational vesicles are found, an ultrasonography is indicated. In the last two instances, fetal resorption has frequently been observed, which may warrant further examinations and sequential ultrasonographic examinations during the rest of the pregnancy. Furthermore, in cases of only one or two gestational vesicles the chance and risk of a prolonged pregnancy have to be discussed with the owner.

247 CHAPTER • 247 Ovarian and Estrous Cycle Abnormalities

Autumn P. Davidson

Edward C. Feldman

Deviation from anticipated, typical estrous cycle events in a bitch intended for breeding can prompt owners to bring their dogs to a veterinarian for evaluation. The canine reproductive cycle is categorized into four distinct phases, each having particular behavioral, physical, and endocrinologic characteristics. Considerable variation exists within the normal canine reproductive cycle, breeders commonly interpret such variation as an indication that an abnormality exits. The clinician must differentiate bitches having normal estrous cycles with unexpected patterns from those with true abnormalities. Detection of individual variation within the normal range of events in a fertile bitch can be crucial to providing effective counseling concerning breeding management. Additionally, evaluation of the estrous cycle for actual abnormalities is an important component in assessing the apparently infertile bitch. Variations from normal estrous cycle events in the bitch can sometimes be traced to specific ovarian disorders.

247.1 THE NORMAL CANINE ESTROUS CYCLE

The interestrous interval normally varies from 4.5 to 10 months in duration, with 7 the average. The anestrus phase of the interestrous interval is marked by reproductive inactivity, uterine involution, and endometrial repair. The normal bitch is neither attractive nor receptive to male dogs. Minimal mucoid vaginal discharge is present, and the vulva is not swollen. Vaginal cytology is scant, characterized by small parabasal cells, with occasional non-toxic neutrophils and may have small numbers of mixed bacteria present. Viewed endoscopically, the vaginal mucosal folds are flat, thin, and pale red. The termination of anestrus (onset of proestrus) follows the pulsatile, hypothalamic gonadotropin-releasing hormone (GnRH) induced secretion of the pituitary gonadotropins, follicle-stimulating hormone (FSH), and luteinizing hormone (LH). Such pulsatile GnRH secretion is a physiologic requirement of gonadotropin release. Following GnRH stimulation during late anestrus, pituitary gonadotrophs release LH in a rapid, transitory pattern and FSH in a slow, sustained pattern. Mean levels of both FSH and LH rise moderately during late anestrus. At the termination of anestrus, the pulsatile release of LH increases, which precedes and likely amplifies ovarian folliculogenesis during proestrus. Estrogen levels are basal (5 to 10 pg/mL) and progesterone levels at nadir (<1 ng/mL) in late anestrus. Anestrus normally lasts from 1 to 6 months.[1,2]

During proestrus, the bitch attracts male dogs but is still not receptive to breeding. She may become more playful or passive concerning the male as proestrus progresses. A serosanguineous-hemorrhagic vaginal discharge of uterine origin is present and the vulva is mildly enlarged and turgid. The microscopic appearance of exfoliated vaginal epithelial cells shifts over a period of 4 to 7 days from small parabasal cells to small then large intermediate cells, superficial-intermediate cells, and finally superficial (cornified) epithelial cells. These changes in the vaginal cells reflect the degree of estrogen influence on the vaginal mucosa. The vaginal wall becomes thickened under the progressive influence of estrogen, in preparation for copulation. Red blood cells are usually but not invariably present on the vaginal smear.

Endoscopically, the vaginal mucosal folds appear edematous, pink and rounded. FSH and LH levels are low during most of proestrus, rising during preovulatory surges. Estrogen rises from basal anestrus levels to peak levels (50 to 100 pg/dl during late proestrus), while progesterone remains basal (<1 ng/mL) until rising (2 to 4 ng/mL) in conjunction with the LH surge. The LH surge generally lasts only 12 to 24 hours in the bitch. Occasionally, more than one LH surge occurs, the one associated with a concurrent rise in serum progesterone

level reaching 2 to 3 ng/mL is likely associated with ovulation. Proestrus lasts from 3 days to 3 weeks and averages 9 days. The follicular phase of the ovarian cycle coincides with proestrus and early estrus.[1,3]

During estrus, the normal bitch displays receptive or passive behavior with a male dog, which enables breeding. Serosanguineous to hemorrhagic vaginal discharge diminishes to variable degrees. Vulvar enlargement and edema tends to be maximal but the vulva is soft. Vaginal cytology usually consists of 80% to 100% superficial cells. Red blood cells tend to diminish but may persist throughout estrus. Endoscopically, vaginal mucosal folds become progressively wrinkled or crenulated, the degree correlating with oocyte maturation to a fertilizable stage. Plasma estrogen progressively declines to basal concentrations, achieved as estrus ceases. Progesterone concentrations steadily increase (usually 4 to 10 ng/mL at ovulation), marking the onset of the luteal phase of the ovarian cycle.

Estrus lasts 3 days to 3 weeks, with an average of 9 days. The receptive behavior of estrus may precede or follow shortly after the LH peak. Duration of receptivity is variable and may not coincide precisely with the fertile period. Receptive behavior reflects decreasing estrogen and increasing progesterone concentrations. Ovulation of primary (infertile) oocytes begins approximately 1 to 2 days after the LH surge; oocyte maturation occurs over the following 1 to 3 days. The life span of secondary (fertile) oocytes is 2 to 3 days. The resultant fertile window in the bitch, during which time breeding is most likely to result in conception, is between 3 and 7 days after the LH surge, or after the initial day progesterone reaches 2 to 3 ng/mL.[1–3]

During diestrus, the normal bitch becomes refractory to breeding and gradually less attractive to male dogs. Vaginal discharge diminishes, often becoming mucoid and mildly suppurative and odorous before disappearing, and vulvar edema turgid, then slowly regressing. Vaginal cytology is abruptly altered by the reappearance of parabasal epithelial cells and, frequently, neutrophils. Vaginal cytology on the first day of diestrus has less than 50% superficial cells. Endoscopically, vaginal mucosal folds appear flattened, pink, and flaccid. Plasma estrogen concentrations are low during diestrus, except for a mild rise reported in the pregnant bitch prior to parturition. Plasma progesterone concentrations steadily rise during the first few weeks of diestrus to a plateau of 15 to 80 ng/mL, before progressively declining in late diestrus. Progesterone secretion is dependent on both pituitary LH and prolactin secretion. Proliferation of the endometrium and quiescence of the myometrium occur under the influence of progesterone.

Diestrus usually lasts 2 to 3 months in the absence of pregnancy. Parturition terminates pregnancy 64 to 66 days after the LH peak (or the initial rise in progesterone), or 56 to 58 days after the onset of diestrus as determined by vaginal cytology. Gestational length may be related to litter size and parity.[4] Prolactin concentrations increase in a reciprocal fashion to declining progesterone concentrations as diestrus ends. Prolactin concentrations are higher in pregnant bitches. Mammary ductal and glandular tissues increase in response to prolactin, which makes lactation a normal event even in the non-pregnant state (pseudopregnancy).[1–3]

247.2 NORMAL VARIATIONS IN THE CANINE ESTROUS CYCLE

During evaluation of a bitch for estrous cycle abnormalities, the medical history, signalment, and husbandry of a bitch should be taken into account along with the specific reproductive history, physical examination findings, and results of clinical testing. Following the bitch over time, through one estrous cycle, is often necessary to reach a diagnosis.

247.2.1 Delayed Puberty

The onset of the first estrous cycle occurs after a bitch attains 70% of her adult height and body weight. Small breeds generally begin their first estrous cycle between 6 and 10 months of age, whereas large breeds may normally begin as late as 18 to 24 months. Family histories (dam and female siblings) can help predict the onset of reproductive activity. Efforts at differentiating delayed puberty from an actual failure to have reproductive cycles should be postponed until a bitch is at least 2 to 2.5 years old. Bitches with delayed puberty have normal reproductive cycles once initiated.

1650 1651

247.2.2 Silent Heat Cycles

The occurrence of a silent heat cycle needs to be ruled out during evaluation of a bitch for a reported failure to have estrous cycles. Fastidious bitches with minimal vulvar swelling, vaginal discharge, or behavioral changes may have estrous cycles that escape human detection, especially in the absence of a male dog. Estrous cycles tend to become more apparent as the bitch ages. Performing weekly vaginal cytologies, housing the bitch near an intact male, or using white bedding can aid in prospective detection of a silent heat, permitting ovulation timing and breeding. Performing monthly progesterone assays permits retrospective identification of estrus but will not facilitate breeding that cycle. Silent heat cycles need to be differentiated from true primary anestrus. True primary anestrus in the bitch that fails to experience an estrous cycle is most likely due to a disorder of sexual development, and is uncommon.[3]

247.2.3 Split Heat Cycles

Bitches experiencing split heat cycles, in which proestrus and possibly early estrus occur without progression, may be thought to have abnormally short cycles, lack of sexual receptivity, or infertility if breedings were forced or artificial insemination performed. Waves of folliculogenesis with increased estrogen production but without ovulation occur in split heats. Follicular atresia follows, no luteal phase with progesterone production occurs, and normal sexual receptivity fails to develop. These cycles typically occur in young bitches and are characterized by periods of hemorrhagic vaginal discharge typical of proestrus, attractiveness to males, and usually no receptivity. In young bitches, split cycles are thought to be due to immaturity. These cycles may also occur in mature bitches with a history of normal past cycles, usually in association with stress. Increased endogenous cortisol levels associated with stress (travel, shipping, kenneling) may inhibit the LH surge and associated ovulation.

After a period of 2 to 10 weeks, another proestrus typically begins, which may or may not proceed to ovulation. Eventually, most young bitches experiencing split heats progress through a normal estrus to diestrus. The condition is not associated with reproductive pathology in the young or stressed bitch, and no treatment is recommended. Breeding the bitch thought to have been previously stressed in familiar surroundings is advised. Serial vaginal cytology documenting the influence of estrogen on vaginal mucosa early in the cycle, and progesterone assays performed 1 to 2 weeks later (<2 ng/mL) documenting folliculogenesis without ovulation or luteinization confirm the diagnosis of a split heat. Occasionally split cycles occur on a regular basis in mature individual bitches, making them difficult to breed, and likely associated with abnormalities of the hypothalamic/pituitary/ovarian axis.

247.2.4 Management Errors

Bitches examined because they have failed to permit breeding or to conceive after a forced breeding or artificial insemination during the perceived fertile period need to be evaluated for kennel management errors. The timing of receptive and fertile periods during estrus varies significantly among normal bitches and even in individual bitches during different estrous cycles. These periods may not correlate with the handler's choice of predetermined breeding dates, typically between days 10 to 14 after the onset of vaginal bleeding. Ovulation timing protocols utilizing serial vaginal cytology, repeated vaginoscopy, and serum progesterone and LH concentrations are useful in identifying the actual fertile period when breeding should occur.[5] Behavioral or physical problems can interfere with acceptance of a male for breeding. Dominant bitches exposed to an inexperienced male may not allow breeding even during the appropriate time. Vulvar or vaginal abnormalities such as strictures and septate bands, and vaginal hyperplasia may make natural breeding painful and result in a bitch refusing to permit copulation even when in estrus[6] (Figure 247-1). The pre-breeding veterinary examination permits early detection of such anatomic problems, enabling their correction or adjustment in breeding plans (artificial insemination versus natural) before the onset of proestrus.

247.3 PATTERNS OF ABNORMAL ESTROUS CYCLES

Abnormal estrous cycles can be categorized and simplified into several patterns that reflect either a prolongation or abbreviation of a phase of the cycle, or an alteration in the normal sequence of events. An owner's interpretation of a bitches behavior and physical characteristics may not equate with the actual physiologic events, which necessitates prospective documentation of the cycle through vaginal cytology, vaginoscopy, behavioral analysis, and assessment of serum progesterone and LH concentrations.

247.3.1 Prolonged Proestrus or Estrus

Prolonged proestrus or estrus occurs when a bitch displays vaginal bleeding (of uterine origin) for more than 21 to 28 consecutive days, accompanied by attractiveness to males. Greater than 80% to 90% superficial cells are found on vaginal cytology. Such bitches may or may not be receptive to breeding. Prolonged proestrus and/or estrus most likely results from persistent secretion of estrogens with or without small elevations in progesterone secretion. If secreted, progesterone enhances the presence of sexual receptivity.

Endogenous sources of prolonged estrogen exposure in the bitch, with or without progesterone, include ovarian follicular cysts and secretory neoplasias.[7] Secretory, anovulatory follicular ovarian cysts tend to be solitary, lined with granulosa cells and exceed normal preovulatory follicles in size, ranging from 1 to 5 cm in diameter (Figure 247-2). Bilateral follicular cysts may indicate a problem with the hypothalamic pituitary ovarian axis. Follicular cysts tend to occur in bitches less than 3 years of age. Ovarian neoplasias capable of producing estrogen occur and include tumors of epithelial origin (cystadenomas and adenocarcinomas) as well as tumors of gonadal-stromal origin (granulosa-theca cell tumors).[8] Ovarian neoplasia tends to occur in bitches older than 5 years of age. Ovarian tumors can occur unilaterally or, less commonly, bilaterally. Functional ovarian neoplasia and cystic ovarian pathology can occur simultaneously (Figure 247-3). Cysts found in the contralateral ovary, and endometrial hyperplasia that accompany a functional tumor occur most frequently with gonadal-stromal origin tumors.[9]

Figure 247-1 Vaginoscopic view of a septate band of tissue in the caudal vaginal of an estrus bitch exhibiting pain during breeding efforts. The band is retracted with a spay hook.

Figure 247-2 Functional, nonovulatory follicular ovarian cysts found in a Mastiff bitch that has been experiencing estrus for greater than 3 months.

There are few differential diagnoses for prolonged vaginal bleeding. Vaginal bleeding secondary to infection, inflammation or neoplasia of the genitourinary tract, a vaginal foreign body, or a coagulopathy should be differentiated from prolonged proestrus or estrus. Excessive exogenous administration of estrogen may be encountered when a bitch is treated for urethral sphincter incompetence with diethylstilbestrol (DES), or from attempts to prevent unwanted pregnancy using DES or estradiol cypionate. Recognized sequela to chronic estrogen exposure include bone marrow dyscrasias, predisposition to the cystic endometrial gland hyperplasia/pyometra complex, and the development of ovarian cysts.[7–9]

After confirmation of naturally occurring hyperestrogenism is obtained through vaginal cytologies (they can be confirmed with serum estrogen level measurement), abdominal ultrasonography is recommended in the attempt to identify an ovarian follicular cyst or functional neoplasia (Figure 247-4). Normal preovulatory follicles measure 4 to 9 mm in diameter, smaller than follicular cysts and most functional neoplasia.[10] Analysis of the estrogen and progesterone levels in fluid from abnormal cystic ovarian structures obtained via ultrasound guidance and histologic analysis of tissues obtained surgically can confirm the diagnosis.

Figure 247-3 Ovarian carcinoma, right ovary (ruler), accompanied by ovarian follicular cysts, left ovary, in a Boxer bitch that has been experiencing estrus for greater than 2 months.

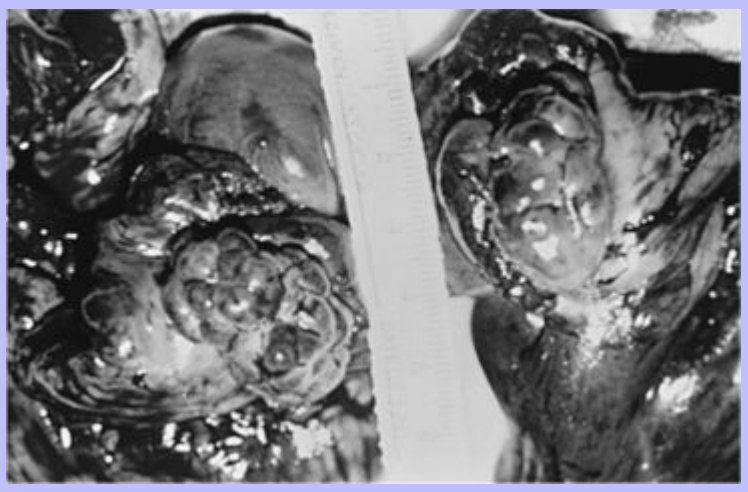

Figure 247-4 Ultrasonographic appearance of a functional, estrogen secreting, nonovulatory ovarian follicular cysts.

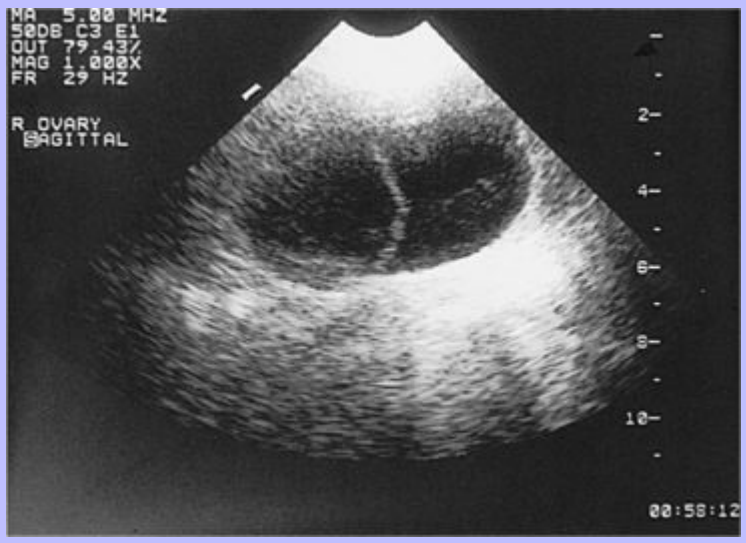


Because follicular cysts may spontaneously undergo atresia or luteinization, not all bitches experiencing prolonged proestrus or estrus require treatment. Progression of the follicular cyst to an atretic follicle or a corpora lutea can be monitored ultrasonographically, via vaginal cytologies, and by serum estrogen and progesterone levels. Therapy aimed at terminating prolonged proestrus or estrus becomes necessary if spontaneous regression fails to occur, vaginal bleeding is a continuing nuisance, estrus behavior and the attraction of males is unacceptable, or other complications develop (blood loss anemia, marrow dyscrasias, vaginal hyperplasia) (Figure 247-5). Medical and surgical options exist for treatment of persistent pathologic follicular cysts. Medical therapies should not place the reproductive health of the bitch at risk. Progesterone treatment of bitches with functional follicular cysts puts the bitch at increased risk for the development of cystic endometrial hyperplasia/pyometra, and is not advised. The use of GnRH (50 to 100 ug/bitch IM q24-48h for up to 3 doses) or human placental gonadotropin (H.C.G.; 11 IU/lb; 22 IU/kg, IM, q24-48h) has been advocated as affective in inducing cyst regression or luteinization, although reported success rates for either vary.[3,7] GnRH does not appear to be antigenic in the bitch and may be the preferred treatment. Successful induction of cyst regression or luteinization is reflected by a reduction in vaginal discharge, change in vaginal cytology reflecting reduced estrogen effect, diminished attractiveness to males, and normalization of behavior. Serum estrogen concentrations fall, and increased progesterone concentrations occur if luteinization results. Ultrasonographic monitoring of ovarian morphology shows regression of hypoechoic structures.

It has been suggested that failure of medical therapies to resolve prolonged proestrus or estrus indicates that ovarian neoplasia is more likely than a follicular cyst; this has not been our experience.[3,6] Medical treatment of prolonged proestrus or estrus is usually unrewarding and surgical removal of the cyst the most expedient means of managing the problem.[3] Removal of the cyst alone is optimal, but resection of the associated ovary is usually necessary. Histologic evaluation of the removed tissue confirms the diagnosis and, importantly,

permits evaluation for evidence of neoplasia that may warrant additional therapy and a much more negative prognosis (Figure 247-6).[11]

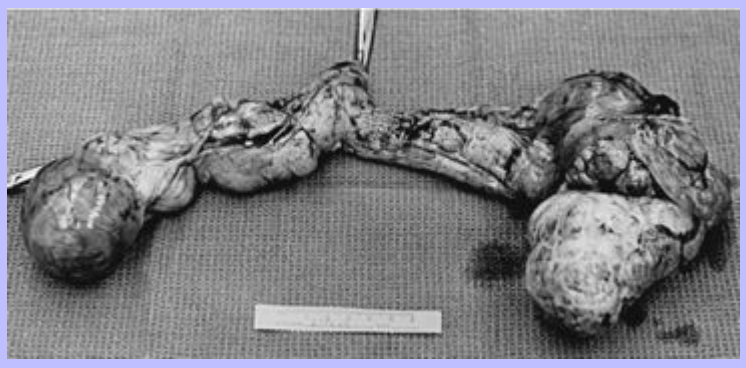
Figure 247-5 Vaginal hyperplasia, present for greater than 3 months in a Mastiff bitch that is experiencing prolonged proestrus/estrus secondary to follicular ovarian cysts.

247.3.2 Prolonged Interestrous Intervals

Bitches exhibiting prolonged interestrous intervals may have prolongation of either anestrus or diestrus. Prolonged anestrus occurs when no ovarian activity occurs for longer than 16 to 20 months in a bitch having previously experienced estrous cycles (secondary anestrus). An actual failure to continue to cycle must be differentiated from silent heats. Underlying disease and iatrogenic causes for failure to cycle should be ruled out by a careful history, physical examination and database. The mechanism by which anestrus is normally terminated in the bitch is not well understood. Dopamine inhibits prolactin secretion. Prolactin levels decrease from late diestrus to late anestrus. Both FSH and LH have been reported as the hormone initiating proestrus folliculogenesis. Dopamine agonists (cabergoline, bromocriptine) can be used to shorten anestrus in both the normal bitch, and in bitches with secondary anestrus of unknown etiology. The mechanism by which dopamine agonists induce proestrus may be a direct reduction in prolactin levels or a direct dopaminergic action on either the gonadotrophic axis or on ovarian gonadotrophin receptors.[12]

A bitch examined for evaluation of prolonged intervals between heat cycles may be under the influence of increased plasma progesterone concentrations (>2 to 5 ng/mL). When plasma progesterone concentrations remain elevated for longer than 9 to 10 weeks, prolonged diestrus is probable. The clinical behavior of the bitch cannot be differentiated from one with prolonged anestrus. The value of vaginal cytologies, serial plasma progesterone levels, and the ultrasonographic appearance of the ovaries and uterus becomes important in establishing a diagnosis.

Figure 247-6 Bilateral ovarian neoplasia.



Prolonged diestrus may occur secondary to the presence of a luteinized (progesterone-secreting) ovarian cyst. The progesterone causes negative feedback to the pituitary/hypothalamic axis, preventing the stimulation of normal ovarian activity. Luteinized cysts can be single or multiple, involving one or both ovaries.[3] Abdominal ultrasonography can identify hypoechoic structure(s) within the affected ovary(ies) (Figure 247-7). Abdominal radiography rarely provides diagnostic information because the cysts are relatively small. Serum progesterone levels greater than 2 to 5 ng/mL confirm the diagnosis. Treatment with prostaglandin F2alpha (PGF2α) usually causes only a transient decline in serum progesterone levels, indicating partial luteolysis. Surgical removal of the cyst(s) with histologic analysis is the recommended treatment. Separation of the cyst from the affected ovary is optimal but is technically difficult, necessitating ovariectomy.[3] Acquiring a uterine biopsy to evaluate the presence and extent of accompanying cystic endometrial hyperplasia is advisable, as it can provide valuable information to the owner concerning future fertility of the bitch (see Figure 247-7). Cystic endometrial hyperplasia, if present, may resolve partially after elimination of the cyst.

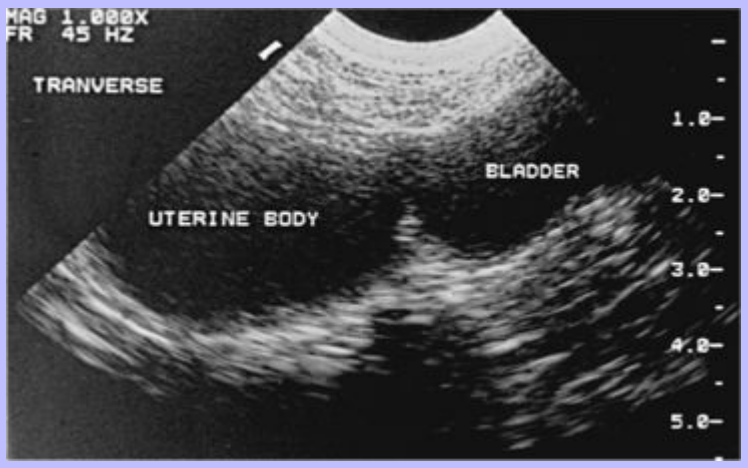
Nonfunctional ovarian cysts may cause failure to cycle due to their mass effect. Rete ovarii cysts and subsurface epithelial structure cysts are examples of nonfunctional ovarian cysts. Increases in plasma estrogen or progesterone concentrations will not be identified, although these cysts have the potential to produce a wide variety of other steroidal compounds without systemic effect.[3] The diagnosis, initially suspected using abdominal ultrasonography, is confirmed by histologic evaluation of surgically removed tissues.

Premature ovarian failure can result in permanent anestrus. Although the functional longevity of the ovaries of bitches is not known, on average the decline in function would not be expected before 7 to 10 years of age. Prolonged anestrus due to premature ovarian failure could be supported by documentation of markedly increased plasma FSH and LH concentrations as would be seen following ovariohysterectomy. Such increases indicate a lack of negative feedback to the pituitary and hypothalamus, without any other identifiable cause for anestrus.[13] Immune mediated oophoritis, diagnosed by ovarian histopathology, could result in prolonged anestrus. A mononuclear infiltrate predominated by lymphocytes, plasma cells and macrophages has been reported to occur in both ovaries in a bitch experiencing estrous cycle abnormalities.[13] This is an extremely rare disorder.

1653

1654

Figure 247-7 Ultrasonographic appearance of cystic endometrial hyperplasia and hydrometra in a Doberman bitch that is experiencing prolonged interestrous intervals, with elevated plasma progesterone concentrations for greater than 4 months, due to a luteinized ovarian cyst.



Hypothyroidism is a potential cause for failure to cycle, but the diagnosis should be well supported by other clinical signs (lethargy, weight gain, bilaterally symmetric alopecia) and clinical pathologic data (hypercholesterolemia, nonregenerative anemia), as well as confirmation of subnormal serum thyroid (total T4 and free T4 by equilibrium dialysis) levels, ideally supported by elevated endogenous TSH levels. Bitches with circulating antithyroid antibodies may have artificially elevated total T4 levels due to cross reactivity. Hypothyroid bitches placed on adequate replacement therapy should begin to cycle within 6 months of becoming euthyroid.[3,14–16] The presence of immune mediated thyroiditis is thought to have a genetic basis in some breeds and may occur with other immune mediated endocrinopathies. The breeding soundness of such bitches should be addressed with clients. Glucocorticoids can feedback on pituitary gonadotrophins FSH and LH, causing a failure to cycle.[16–17] Therefore administration of any steroid medication must be discontinued in a bitch with prolonged anestrus.

247.3.3 Shortened Interestrous Intervals

Bitches with short (less than 4.5 months) interestrous intervals can fail to conceive due to incomplete uterine involution and repair, precluding implantation.[3] Classically, bitches with shortened interestrous intervals are normal in other respects. Ovulation and luteinization occur, the secondary oocyte is fertilized but fails to implant successfully. Documentation of this disorder requires evaluation of serial vaginal cytologies during estrus and diestrus, and plasma progesterone concentrations during the luteal phase of at least two consecutive cycles. Currently, there is no reliable, commercially available, consistent pre-implantation method of confirming fertilization in the dog. The occurrence of folliculogenesis without ovulation (split heat) and hypoluteiodism (premature luteal failure) should be ruled out. Shortened interestrous intervals occur because anestrus is abbreviated. A defect in the hypothalamic-pituitary-ovarian axis may exist, which causes

interference with the normal maintenance of anestrus; an imbalance of dopamine versus prolactin levels has been theorized to contribute to this syndrome. Anestrus can be abbreviated clinically in the normal bitch by the administration of prolactin inhibitors such as cabergoline and bromocriptine.

Intervention should not take place unless the bitch is older than 3 years, because these abnormalities may naturally resolve with maturity. One suggested therapy consists of inducing anestrus through the use of mibolerone, a potent synthetic androgen causing negative pituitary and hypothalamic feedback and ovarian inactivity, for 6 months. Mibolerone must be compounded as it has been taken off the market due to the potential for abuse. The compound is started 6 to 8 weeks after the previous estrus. Potential and predictable side effects include clitoral hypertrophy, mucoid vaginal discharge, atrophy of the glandular endothelium, epiphora, and virilized behavior. The bitch should be bred on the first cycle after discontinuation of the drug, which can occur immediately, or be delayed from 6 to 9 months.[3] Unfortunately, many bitches experience infertility during the first cycle after mibolerone administration, likely due to endometrial atrophy, and then begin to cycle frequently again.

No controlled studies exist that document the efficacy of this protocol, and it is not recommended by the authors. The availability of better, reversible birth control medications for the bitch, with fewer side effects, will improve the ability to treat this disorder. A genetic basis is suspected, and bitches experiencing shortened interestrous intervals likely are not good breeding candidates.

247.3.4 Hypoluteoidism

The maintenance of canine pregnancy requires plasma progesterone concentrations of greater than 1 to 2 ng/mL. Hypoluteiodism, primary luteal failure occurring before term gestation is a potential but not documented cause of abortion in dogs.[3,13,17] Induction of abortion follows reduction of plasma progesterone levels below 2 ng/mL.[3,18] The diagnosis of gestational loss caused by premature luteolysis is difficult and requires documentation of inadequate plasma progesterone concentrations prior to abortion for which no other cause is found. Measurement of precise progesterone concentrations, especially in the critical 1 to 3 ng/mL range, is not accurate using currently available rapid in-house ELISA kits.

Plasma progesterone concentrations diminish in response to fetal death, thus documentation of a low value after an abortion does not establish the diagnosis of hypoluteiodism as the cause for reproductive failure. Administration of progesterone to maintain pregnancy in bitches with primary fetal abnormalities, placentitis, or intrauterine infection can cause continued fetal growth with the possibility of dystocia and sepsis. Administration of progesterone to maintain pregnancy in a bitch not actually requiring therapy can delay parturition, which endangers the life of the bitch and her fetuses and may masculinize, female fetuses.

Bitches with low plasma progesterone concentrations and historical late term loss of pregnancy with no apparent pathology should be evaluated for premature myometrial activity mid gestation, using uterine monitors. Elaboration of prostaglandins from the endometrium and placenta associated with premature myometrial activity can result in declining progesterone levels. Pharmacologic intervention to decrease myometrial activity may be indicated, using tocolytic agents such as terbutaline. Bitches experiencing premature myometrial activity in one pregnancy may or may not exhibit it during subsequent pregnancies. Exogenous progesterone supplementation for bitches with premature labor (not necessary in the authors' experience with appropriate tocolytic therapy) can interfere with normal parturition, and oral progesterone supplementation can be complicated by causing poor lactation (interference with prolactin production), dystocia, and fetal death.[19,20]

247.3.5 Exaggerated Pseudocyesis (Pseudopregnancy)

Nonpregnant bitches showing overt signs of term pregnancy are frequently brought to veterinarians because of concerns about parturition. Symptoms exhibited during overt pseudocyesis include weight gain, mammary gland hyperplasia and lactation, mucoid vaginal discharge, inappetence, restlessness, nesting, and mothering of inanimate objects. Abdominal palpation and ultrasonography can establish the presence or absence of fetuses. Alternatively, owners may be concerned about bitches showing overt signs of pseudocyesis because they find the behavior or physical symptoms objectionable in a bitch they know is not pregnant.

Pseudocyesis is an exaggeration of the normal physiologic phenomena experienced by any nonpregnant bitch completing the luteal portion of an estrous cycle. These signs are the result of progesterone concentrations declining and prolactin increasing. The clinical expression of pseudocyesis varies from indiscernible to (rarely) potentially serious. Clinical signs of pseudocyesis usually are reported from 6 to 12 weeks after estrus. Signs of pseudocyesis are often reported by owners when giving reproductive histories as if its occurrence indicates a reproductive disorder, when in fact, pseudocyesis probably establishes that the bitch has a normal hypothalamic-pituitary-ovarian axis and estrous cycle.

Bitches that exhibit signs consistent with a diagnosis of pseudocyesis are probably under the influence of prolactin. Similar concentrations can be demonstrated in bitches that have no clinical signs, suggesting that the former may have increased target organ concentrations or heightened peripheral sensitivity to the hormone.[3] The condition is self limiting, usually regressing in 1 to 3 weeks, and therapy is not recommended unless the signs are unusually prolonged or pronounced, such as causing mastitis. Unusually persistent cases of inappropriate lactation should be evaluated for hypothyroidism, in which excess TRH may, in turn, cause increases in prolactin.

1654 1655

Table • 247-1 Drug Appendix

GENERIC	TRADE	DOSAGE	ROUTE	FREQUENCY	DESCRIPTION
GnRH	Cystorelan	50–100 ug	IM	q 24-48h ×3	Hypothalamic releasing hormone
h.c.g.	Gonamone	11 IU/lb (22 IU/kg)	IM	q 24-48h	Placental gonadotropin
PGF2α	Lutalyse	0.05-0.10 mg/lb (0.10-0.20 mg/kg)	SC	q 8h	Natural prostaglandin
Mibolerone	Pseudocyesis:	0.008 mg/lb (0.016 ug/kg)	PO	q 24h ×5	Synthetic androgen
Bromocriptine		0.005-0.05 mg/lb (0.01-0.10 mg/kg)		q 24h	Ergot alkaloid divided
Carbergoline		2.5 ug/lb (5.0 ug/kg)		q 24h or divided bid ×3–5	Ergot alkaloid

Therapy, when recommended, is usually directed at decreasing or eliminating lactation. Therapy is pursued to reduce the likelihood of mastitis occurring secondary to milk stasis, or to diminish lactation-induced household soiling. Minimal measures are recommended. Mammary stimulation, via licking, mothering behavior, or warm or cold compressing should be discontinued. Dopamine antagonists, of which phenothiazines are a class, enhance prolactin secretion and should not be administered. Mild sedation with a non-phenothiazine tranquilizer may be helpful.[3]

A variety of hormonal and medical therapies have been employed to reduce or stop lactation in pseudopregnant dogs. Side effects, in most cases, outweigh the benefit of these medications. Therapy with gonadal hormones, progesterone, estrogen, or testosterone is not recommended due to complications of repetitive cycles of pseudocyesis, symptoms of proestrus or estrus, and virilization behavior, respectively. The compounded synthetic androgen mibolerone, administered at 0.008 mg/lb (0.016 mg/kg) orally once daily for 5 days, has successfully abbreviated the signs of pseudocyesis in approximately 50% of treated cases, although this medication also may cause virilization.[21] Ergot alkaloids are potent prolactin inhibitors (dopaminergic) and can be used to abbreviate exaggerated pseudocyesis. Bromocriptine can be administered at 0.005 to 0.05 mg/lb/day (0.01 to 0.10 mg/kg/day) in divided doses until lactation ceases. Vomiting, depression and anorexia are commonly reported side effects, usually more problematic than the lactation. Carbergoline, administered at 2.5 ug/lb/day (5.0 ug/kg/day), given divided or once daily for 3 to 5 days effectively decreases prolactin concentrations and diminishes signs of pseudocyesis with fewer side effects, but is expensive and must be compounded for use in all but giant breeds. Permanent avoidance of clinical pseudocyesis requires ovariohysterectomy.

248 CHAPTER • 248 Abnormalities in Pregnancy, Parturition, and the Periparturient Period

Catharina Linde-Forsberg

248.1 PREGNANCY

248.1.1 Physiologic Changes and Clinical Monitoring

Maternal physiologic alterations during pregnancy are due to increased metabolic demands. Blood volume increases by 40%, which provides an adequate reserve to compensate for the large quantities of blood and fluids lost at parturition. The volume increase is primarily plasma with a resulting hemodilution (the hematocrit is around 30% at term). An increase in cardiac output occurs, caused by enhanced heart rate and stroke volume. The functional residual capacity of the lungs is decreased by anterior displacement of the diaphragm by the gravid uterus, and oxygen consumption during pregnancy increases by 20%. Pregnant animals also have delayed gastric emptying due to decreased gastric motility and displacement of the stomach.

It is recommended to examine bitches and to obtain radiographs at about 45 days of gestation. This allows the veterinarian to assess the health of the bitch, confirm pregnancy, count fetuses, and answer questions. Ultrasound is less exact for determining the number of fetuses but is excellent for assessing fetal viability and can be performed with accuracy from the twenty-fourth day.

248.1.1.1 Gestation Length

Apparent gestation length in the bitch averages 63 days, with a variation from 56 to 72 days if calculated from the first mating.[1] This surprisingly large apparent variation is mainly due to the long and variable behavioral estrus period of the bitch. Gestation length is quite predictable when instead calculated either from the preovulatory surge of luteinizing hormone (LH) being 65 ± 1 days, from the day of ovulation being 63 ± 1 days, or from the time of fertilization being 60 ± 1 days.[2,3] There exists conflicting data in the literature regarding whether a correlation exists between breed or body weight, and/or litter size and length of gestation.

248.1.1.2 Prediction of Parturition Day

The ability to determine gestational age and to predict the day of parturition in the bitch is of considerable clinical importance, especially in case of threatening abortion, prolonged gestation, or when the bitch is scheduled for elective caesarean section or suffers from dystocia. B-mode ultrasonography has been used to assess the diameter of pregnancy structures and to estimate fetal size during pregnancy. Inner chorionic cavity diameter on the eighteenth to the thirty-seventh day from ovulation and fetal head diameter on the thirty-eighth day to parturition show the best correlation to gestational age and day of parturition.[4] Other fetal structures used to time pregnancies using ultrasonography are fetal limb buds, first detectable at the thirty-third to the thirty-fifth day; eyes, kidney, and liver at the thirty-ninth to the forty-seventh day; and intestine at the fifty-seventh to the sixty-third day.[1] Using radiography the fetal skeleton is rarely visible before the forty-second day; the skull on the forty-fifth to the forty-ninth day; pelvic bones on the fifty-third to the fifty-seventh day; teeth on the fifty-eighth to the sixty-third day.[1] Serum cortisol levels increase at the time of delivery and remain high for 12 hours to reach basal levels again after 36 hours.[5] Levels of

15-ketodihydro-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) increase 24 hours before parturition and again at the onset of whelping.[5] In most bitches, parturition occurs 65 ± 1 days from the LH-peak, which coincides with the initial sharp rise in serum progesterone concentrations to greater than or equal to 4.5 nmol/L (≥ 1.5 ng/mL). The accuracy of parturition day prediction within an interval of ± 1, ± 2, and ± 3 days using prebreeding serum progesterone concentrations was 67%, 90%, and 100%, respectively, and was not influenced by body weight or litter size.[6] The fact that serum progesterone levels decrease significantly from 12 to 15 nmol/L (4 to 5 ng/mL) to below 6 nmol/L (2 ng/mL) starting 24 hours before the onset of whelping can also be used to predict parturition in the late gestational stage.

248.2 DISORDERS DURING PREGNANCY

248.2.1 Early Fetal Loss and Abortion

The incidence of early embryonic and fetal death (before 45 days of pregnancy) and spontaneous abortion in the bitch is not known and is difficult to determine because resorption of conceptuses may occur until the forty-fifth day of pregnancy without noticeable signs, or the bitch may consume aborted fetuses. However, early pregnancy diagnosis using ultrasonography, which is becoming increasingly popular, indicates that fetal resorption is a frequent occurrence in the bitch.

248.2.2 Infectious Agents

Hemorrhage from the genital tract often precedes abortion caused by a bacterial infection. This may be due to an effect of bacterial toxins on the placenta and a release of $PGF_{2\alpha}$ causing the uterus to contract and expel its contents. The underlying cause of the hemorrhage should be diagnosed. Antibiotics, anti-inflammatory or tocolytic drugs (e.g., terbutaline), or both should be administered in an attempt to prevent the abortion. It should be explained to the owner that the bitch can abort some fetuses but may carry the remainder of the litter to term; therefore the bitch should be examined for the presence of any remaining fetuses after cessation of treatment.

248.2.2.1 Brucella Canis

Abortion caused by *B. canis* usually occurs between 45 and 55 days of gestation and is accompanied by a highly contagious brown to greenish-gray vaginal discharge that lasts for 1 to 6 weeks. Infected bitches may not exhibit other clinical signs. *B. canis* may also cause conception failure, fetal death, and absorption in early stages of gestation or the birth of weak, infected puppies. The infection is chronic and mostly asymptomatic in adult animals. Infected animals have intermittent bacteremia and shed bacteria through body fluids. Diagnosis is most commonly based on serologic testing, bearing in mind that it can take several months after infection before antibody titers rise and that antibiotic treatment may create false-negative test results. Additionally, surface antigens of *B. canis* cross-react strongly with antibodies to several other nonpathogenic bacterial species. Blood cultures are therefore strongly recommended before declaring an animal infected.

248.2.2.2 Toxoplasma Gondii and Neospora Caninum

T. gondii and *N. caninum* are both tissue cyst-forming protozoan microorganisms that are vertically transmitted to puppies if a bitch is infected during pregnancy. Infected bitches usually remain clinically

normal, but the puppies are severely affected. Toxoplasmosis is known to cause fetal death and is a rare cause of abortion in dogs. Premature birth, stillbirth, and the birth of weak puppies have also been reported due to toxoplasmosis. Neosporosis causes fatal encephalomyelitis and polymyositis in neonatal puppies infected in utero and has experimentally been shown to cause fetal death and resorption.[7]

248.2.2.3 Canine Herpesvirus

The canine herpesvirus is species specific. In experimental studies it has been demonstrated that the effect of an infection is dependent on stage of pregnancy when infection occurs. Infection in early stages causes fetal death and mummification; in midpregnancy it may result in abortion and in later stages premature birth. More common in naturally occurring cases is that the puppies are born apparently healthy but become ill during the first 1 or 2 weeks and succumb within days. Often the whole litter is affected; however, some of the puppies may survive but develop defective vision, deafness, neuromuscular disorders, or kidney malfunction at 7 or 8 months of age. Normally immunity is incurred, and bitches that have lost a litter due to herpesvirus infection subsequently give birth to normal litters. Canine herpesvirus is presumed to be enzootic in dogs all over the world and the seroprevalence is as high as 46% in some European countries, the incidence not being higher in breeding kennels than among nonbreeding dogs.[8] Herpesvirus has been isolated from 67% of infertile and aborting bitches in those countries, but it is not clear whether it is the virus itself or a combination of several agents that cause the disturbances.

1656

1657

248.2.2.4 Hypoluteodism

Inadequate progesterone production by the corpora lutea is a potential cause of fetal death and abortion in some species but has not unequivocally been proven to exist in the dog. A blood sample for progesterone taken at the time of an abortion often will show low concentration due to the luteolytic effects of the prostaglandin release during fetal expulsion; but, if repeated 1 week later, normal for stage levels of progesterone may be found. Any attempts at treating cases of imminent abortion with progestogens should only be done using a short-acting compound, because the bitch cannot deliver a litter when under the influence of high concentrations of progesterone.[1]

248.2.3 Insulin Resistance

The physiologic increased progesterone concentrations typical of diestrus or pregnancy stimulate growth hormone secretion, which in some individuals may cause down-regulation of insulin receptors and inhibition of postreceptor pathways. The condition is typically seen in middle-aged and older bitches that are pregnant or have recently been in estrus. The resulting type II diabetes is usually transient. Once blood progesterone concentration returns to anestrus levels and thus the stimulus for growth hormone secretion declines insulin resistance resolves.

Insulin resistance should be suspected in a bitch with supranormal blood insulin concentrations in the presence of a normal or increased blood glucose concentration.[9] Treatment should be initiated to prevent permanent damage to the pancreas. A poor prognosis exists for the fetuses, which sometimes become undernourished but sometimes instead grow excessively large (due to the excess in glucose), with a poor survival rate. In the bitch, acromegaly may develop as a result of excessive secretion of growth hormone by the progesterone-stimulated mammary gland. Edema, especially of the head, throat, and legs is seen in combination with excessive skin and wrinkling and an increase in interdental spaces. In advanced cases there

may be a change of voice, getting coarse from the edema of the throat. The condition may become life threatening for the bitch, and it is often necessary to interrupt a pregnancy.

248.2.4 Hypoglycemia

Preparturient hypoglycemia in the bitch is rare. Some hypoglycemic dogs may be incorrectly diagnosed as hypocalcemic because this is a more common condition and because they respond to treatment with calcium borogluconate. Affected bitches have been reported to be in late gestation and have a short history of muscle weakness, convulsions, or collapse. Blood testing demonstrates the hypoglycemia.[10–12] The condition improves dramatically after treatment with intravenous glucose solutions and resolves after parturition.

248.2.5 Premature Labor

Premature labor may have infectious causes, but can also occur in the clinically healthy bitch. Hypoluteoidism as a cause for premature uterine contractions has not been clearly demonstrated in the bitch. Short-acting progestational compounds may, however, be given in an attempt to maintain pregnancy. To adequately inhibit premature uterine contractions, tocolytic compounds such as terbutaline, a beta-adrenergic receptor antagonist, should also be administered orally or subcutaneously to effect and should be discontinued 48 hours before the anticipated day of delivery.

248.3 NORMAL PARTURITION

248.3.1 Litter Size

Litter size in dogs ranges from just one puppy in some of the miniature breeds to 15 or more in some of the giant breeds. Litter size is smaller in the young bitch and increases up to 3 to 4 years of age, decreasing again as the bitch gets older. A litter size of only one or two puppies predisposes to dystocia and thus fetal death, because of insufficient uterine stimulation and large puppy size (i.e., *single-puppy syndrome*).[13] This can be seen in dog breeds of all sizes. Breeders of the miniature breeds tend to accept small litters but should be encouraged to breed for litter sizes of at least three to four puppies to avoid this complication.

248.3.2 Physiology of Parturition

An understanding of the course and control of normal parturition (eutocia) is necessary for the diagnosis and treatment of abnormal parturition (dystocia). Studies of canine parturition and extrapolations from other species provide information on the physiologic and endocrinologic changes important for normal parturition. Stress produced by the reduction of the nutritional supply by the placenta to the fetus stimulates the fetal hypothalamic-pituitary-adrenal axis, resulting in release of adrenocorticosteroid hormone, and it is thought to be the trigger for parturition. An increase in fetal and maternal cortisol is believed to stimulate the release of $PGF_{2\alpha}$, which is luteolytic (from the fetoplacental tissue), resulting in a decline in plasma progesterone concentration. Withdrawal of the progesterone blockade of pregnancy is a prerequisite for the normal course of canine parturition; bitches given long-acting progesterone during pregnancy fail to deliver.[1] Concurrent with the gradual decrease in plasma progesterone concentration during the last 7 days before whelping, a progressive qualitative change occurs in uterine electrical activity. In addition, a significant increase in uterine activity takes place during the last 24 hours before parturition with the final fall in plasma progesterone concentration to below 6 nmol/L (2 ng/mL).[1,14] The change in the estrogen-to-progesterone ratio is probably a

major cause of placental separation and cervical dilation, although in the dog, estrogens have not been unambiguously shown to increase before parturition as they do in many other species. Estrogens sensitize the myometrium to oxytocin, which in turn initiates strong contractions in the uterus when it is not under the influence of progesterone. Sensory receptors within the cervix and vagina are stimulated by the distention created by the fetus and the fluid-filled fetal membranes. This afferent stimulation is conveyed to the hypothalamus and results in release of oxytocin during second-stage labor. Afferents also participate in a spinal reflex arch with efferent stimulation of the abdominal musculature to produce abdominal straining. Relaxin causes the pelvic soft tissues and genital tract to relax, which facilitates fetal passage. In the pregnant bitch, this hormone is produced by both ovary and placenta, increasing gradually over the last two thirds of pregnancy.[15] Prolactin, the hormone responsible for lactation, starts to rise 3 to 4 weeks after ovulation and surges dramatically with the abrupt decline in serum progesterone just before parturition.[1,5]

248.3.3 Signs of Impending Parturition

Relaxation of the pelvic and abdominal musculature is a consistent but subtle indicator of impending parturition. The most consistent change is the drop in rectal temperature caused by the final abrupt decrease in progesterone concentration. The last week before parturition the rectal temperature of the bitch fluctuates to drop sharply 8 to 24 hours before parturition and 10 to 14 hours after the concentration of progesterone in peripheral plasma has declined to less than 6 nmol/L (2 ng/mL).[1,13] To properly assess the prepartum drop in body temperature, measurements should be made every 1 to 2 hours while the temperature decreases and less frequently when the temperature is seen to increase again. The drop in rectal temperature is individual but also may depend on body size. Thus in miniature breed bitches, it can fall to 35° C (95° F), in medium-sized bitches to around 36° C, whereas it seldom falls below 37° C (96.8° F) in bitches of the giant breeds. This difference is probably an effect of the surface area-to-body volume ratio. Several days before parturition the bitch may become restless, seek seclusion, or become excessively attentive, and she may refuse all food. She may exhibit nesting behavior 12 to 24 hours before parturition, concomitant with increasing frequency and force of uterine contractions. Shivering may be an attempt to increase body temperature. In primiparous bitches, lactation may be established less than 24 hours before parturition, whereas after several pregnancies colostrum can be detected as early as 1 week prepartum.

1657 1658

248.3.4 Stages of Parturition

Parturition is divided into three stages, with the last two stages being repeated for each puppy delivered.

248.3.4.1 First Stage

The duration of the first stage is usually 6 to 12 hours. It may last 36 hours, especially in a nervous primiparous animal; however, for this to be considered normal, the rectal temperature must remain low. Vaginal relaxation and dilation of the cervix occur during this stage. Intermittent uterine contractions, with no signs of abdominal straining, are present. The bitch may appear uncomfortable, and the restless behavior may become more intense. Panting, tearing up and rearranging of bedding, shivering, and occasional vomiting may be seen. Some bitches show no behavioral evidence of first-stage labor. The inapparent uterine contractions increase both in frequency and intensity toward the end of the first stage. During pregnancy the orientation of the fetuses within the uterus is 50% heading caudally and 50% cranially, but this changes during first-stage labor when the fetus rotates on its long axis, extending its head, neck, and limbs, resulting in 60% to 70% of puppies being born in anterior and 30% to 40% in posterior

presentation.[16,17] The fluid-filled fetal membranes are pushed ahead of the fetus by the uterine-propulsive efforts and dilate the cervix.

248.3.4.2 Second Stage

The duration of the second stage is usually 3 to 12 hours (in rare cases 24 hours). At the onset of second-stage labor the rectal temperature rises to normal or slightly above normal. The first fetus engages in the pelvic inlet, and the subsequent intense, expulsive uterine contractions are accompanied by abdominal straining. On entering the birth canal, the allantochorionic membrane may rupture and a discharge of some clear fluid may be noted. Covered by the amniotic membrane, the first fetus is usually delivered within 4 hours after onset of second-stage labor. Normally the bitch will break the membrane, lick the neonate intensively, and sever the umbilical cord. At times the bitch will need some assistance to open the fetal membranes to allow the newborn to breathe, and sometimes the airways will have to be emptied of fetal fluids. The umbilicus can be clamped with a pair of hemostats and cut with a blunt scissors to minimize hemorrhage from the fetal vessels, leaving about 1 cm of the umbilicus. In case of continuing hemorrhage the umbilicus should be ligated.

248.3.4.2.1 Diagnosing second-stage labor

It is crucial that the veterinarian is able to determine whether the bitch is in the second stage or still in first stage of labor. Inexperienced breeders tend to get nervous during a bitch's first-stage labor, not fully understanding the function of this preparatory stage of parturition during which uterine contractions, the softening of the birth canal, and the opening of the cervix take place.

Three signs indicate that the bitch has entered into second-stage labor:

1. The passing of fetal fluids (first water bag [allantois], bursts)
2. Visible abdominal straining
3. The rectal temperature returning to normal level

If one or more of these signs have been observed, the bitch is in second-stage labor.

In normal labor the bitch may show weak and infrequent straining for up to 2, and at the most 4, hours before giving birth to the first fetus. If the bitch is showing strong, frequent straining without producing a pup, this indicates the presence of some obstruction, and she should not be left for more than 20 to 30 minutes before seeking veterinary advice.

The bitch should be examined for the following reasons:

- If she has greenish discharge but no pup is born within 2 to 4 hours
- If fetal fluid was passed more than 2 to 3 hours previously, but nothing more has happened
- If she has had weak, irregular straining for more than 2 to 4 hours
- If she has had strong, regular straining for more than 20 to 30 minutes
- If more than 2 to 4 hours have passed since the birth of the last puppy and more remain

- If she has been in second-stage labor for more than 12 hours

248.3.4.3 Third Stage

The third stage of parturition, expulsion of the placenta and shortening of the uterine horns, usually follows within 15 minutes of the delivery of each fetus. Two or three fetuses may, however, be born before the passage of their placentas occurs. The bitch should be discouraged from eating more than one or two of the placentas because she may develop diarrhea and vomiting, with risk of aspiration pneumonia. Lochia (i.e., the greenish postpartum discharge of fetal fluids and placental remains) will be seen for up to 3 weeks or more but is most profuse during the first week. Uterine involution is normally completed after 12 to 15 weeks.

The bitch should be examined for the following reasons:

- If all placentas have not been passed within 4 to 6 hours (although placental numbers may be difficult to determine because of the bitch eating them)
- If lochia are putrid or foul smelling
- There is continuing continuing severe genital hemorrhage
- If the rectal temperature is higher than 39.5° C (101.3° F)
- If the general condition of the bitch is abnormal
- If the general condition of the puppies is abnormal

248.3.5 Interval Between Births

Expulsion of the first fetus usually takes the longest. The interval between births in normal uncomplicated parturition is from 5 to 120 minutes.[16,17] In almost 80% of cases the fetuses are delivered alternately from the two uterine horns.[16] When giving birth to a large litter a bitch may stop straining and rest for more than 2 hours between the delivery of two consecutive fetuses. The second-stage straining will then resume, followed again by the third stage, until all the fetuses are born.

248.3.6 Completion of Parturition

Parturition is usually completed within 6 hours after the onset of second-stage labor, but it may last up to 12 hours. It should never be allowed to last for more than 24 hours because of the risks involved both for the bitch and the fetuses.

248.4 DYSTOCIA

248.4.1 Definition

Dystocia is defined as difficult birth or the inability to expel the fetus through the birth canal without assistance.

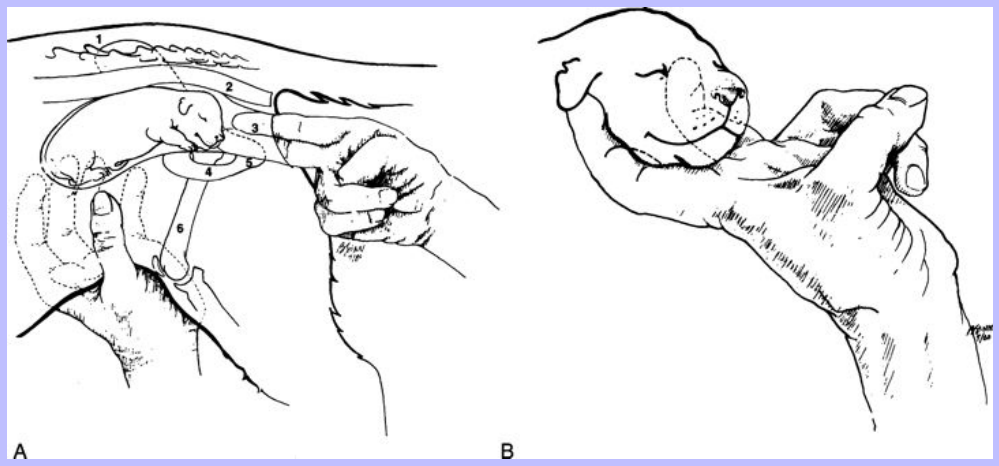
248.4.2 Frequency

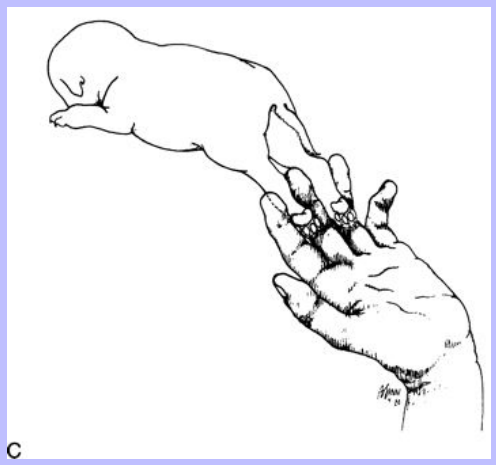
Dystocia is a frequent problem in the dog. The true average incidence of dystocia in the bitch is probably below 5%, but it may amount to almost 100% in some breeds of dogs, especially those of the achondroplastic type and those selected for large heads.[13,17,18]

248.4.3 Clinical Assessment

When a bitch with possible dystocia is examined, an accurate history and a thorough physical examination are important prerequisites for proper management. The three criteria for being in second-stage labor, namely, (1) passage of fetal fluids, (2) visible abdominal straining, and (3) temperature returned to normal, should be assessed. An evaluation of the bitch's general health status should be made and signs of any adverse effects of parturition noted. Observation should be made of the bitch's behavior and the character and frequency of straining, and the vulva and perineum should be examined, noting color and amount of vaginal discharge. Mammary gland development including congestion, distention, size, and presence of milk should be evaluated. Palpation of the abdomen, roughly estimating the number of fetuses and degree of distention of the uterus, should be carried out. Digital examination of the vagina using aseptic technique should be undertaken to detect obstructions and determine the presence and presentation of any fetus in the pelvic canal (Figure 248-1). In most bitches it is not possible to reach the cervix during first stage, but an assessment of the degree of dilation and tone of the vagina may give some indication of the status of the cervix and the tone of the uterus. Pronounced tone of the anterior vagina may indicate satisfactory muscular activity in the uterus, whereas flaccidity may indicate uterine inertia.[19] The character of the vaginal fluids also will indicate whether the cervix is closed, with the production of scant fluid volume that is sticky creating a certain resistance to the introduction of a finger. The cervix is likely open when fetal fluids lubricate the vagina, making the exploration easy. When the cervix is closed the vaginal walls also fit quite tightly around the exploring finger, whereas with an open cervix the cranial vagina palpates more open.

Figure 248-1 *A,* Determination of the fetal disposition when the head has entered the vaginal canal. The bitch should be standing for this procedure. 1, Right wing of ilium; 2, rectum; 3, lumen of vaginal vestibule; 4, right half of pubic symphysis; 5, right wing of ischium; 6, right femur. *B,* The index and middle fingers are used to guide the head and to exert moderate traction in a cranial presentation. *C,* Manual traction as applied in a caudal presentation. The fingers should be positioned proximal to the hocks for best results. (From Shille VM: Diagnosis and management of dystocia in the bitch and queen. *In*: Bojrab MJ [ed]: Current Techniques in Small Animal Surgery. Philadelphia, Lea & Febiger, 1983, p 338; used with permission.)





Radiographic examination is valuable to assess gross abnormalities of the maternal pelvis and number and location of fetuses, to estimate fetal size, and to detect congenital defects or signs of fetal death. In the dead fetus, intrafetal gas will appear 6 hours after death and can be detected radiographically, whereas overlapping of cranial bones and collapse of the spinal column will not be seen until 48 hours have passed after the death of the fetus. Ultrasound examination will determine fetal viability or distress, with normal heart rate being 180 to 240 beats per minute (bpm), decreasing in the compromised fetus. Some bitches brought to veterinarians for dystocia have already delivered all fetuses or were only pseudopregnant. Pseudopregnancy is most commonly diagnosed as lactation without pregnancy, but it may include abdominal contractions, nesting behavior, and changes in personality that convince an owner that the pet is pregnant.

1659
1660

248.4.4 Diagnosis

The range of normal variations observed in dogs at parturition makes recognition of dystocia difficult, especially for the inexperienced observer. The following criteria for dystocia may assist in making the diagnosis:

- The rectal temperature has been down and returned to normal with no signs of labor.
- A green vulvar discharge is seen, but no fetuses have been delivered. (These discharges emanate from the marginal hematoma of the placentas and indicate that at least one placenta is beginning to become separated from the maternal blood supply. They are normal once birth is underway.)
- Fetal fluids were passed 2 to 3 hours earlier, but no signs of labor are noted.
- Labor is absent for more than 2 hours or is weak and infrequent for more than 2 to 4 hours.
- Strong and persistent nonproductive labor occurs for more than 20 to 30 minutes.
- An obvious cause of dystocia is evident (e.g., pelvic fracture or a fetus stuck in the birth canal and partially visible).
- Signs of toxemia (disturbed general condition, general edema, shock) are noted when parturition should be occurring.

Recently, systems for monitoring labor and delivery in the bitch have become commercially available (Veterinary Perinatal Services, Inc., Wheatridge, Colorado).[20] These systems are intended for use by veterinarians or by breeders at home with veterinary guidance. They consist of a uterine tocodynamometer and a fetal Doppler. Using this device the administration of calcium borogluconate and oxytocin can be monitored based on the individual uterine response of the bitch.

248.4.5 Maternal Causes of Dystocia

Traditionally, dystocia is classified as being of either maternal or fetal origin, or a combination of both (Table 248-1; Figures 248-2 and 248-3).

248.4.5.1 Uterine Inertia

Uterine inertia is by far the most common cause of dystocia in dogs. It is classified into *primary* and *secondary* inertia. In primary inertia the uterus may fail to respond to the fetal signals because only one or two puppies exist, which provide insufficient stimulation to initiate labor (the single-puppy syndrome), or because of overstretching of the myometrium by large litters, excessive fetal fluids, or oversized fetuses. Other causes of primary inertia may be an inherited predisposition, nutritional imbalance, fatty infiltration of the myometrium, age-related changes, deficiency in neuroendocrine regulation, or systemic disease in the bitch. Primary complete uterine inertia is the failure of the uterus to begin labor at full term. Primary partial uterine inertia occurs when enough uterine activity exists to initiate parturition, but it is insufficient to complete a normal birth of all fetuses in the absence of an obstruction. Secondary uterine inertia implies that some fetuses have been delivered and the remainder are in utero due to exhaustion of the uterine myometrium caused by obstruction of the birth canal; this condition should be distinguished from primary inertia.

Table • 248-1 Causes of Dystocia in Bitches (182 Cases)

	FREQUENCY (%)
Maternal causes	75.3
Primary complete inertia	48.9
Primary partial inertia	23.1
Birth canal too narrow	1.1
Uterine torsion	1.1
Uterine prolapse	—
Uterine strangulation	—
Hydrallantois	0.5
Vaginal septum formation	0.5
Fetal causes	24.7
Malpresentations	15.4
Malformations	1.6
Fetal oversize	6.6
Fetal death	1.1

(From Darvelid AW, Linde-Forsberg C: Dystocia in the bitch: a retrospective study of 182 cases. J Small Anim Pract 35:402–407, 1994.)

248.4.5.1.1 Management

In cases of primary uterine inertia, the owners should initially be instructed to try to induce straining by actively exercising the bitch, for instance, by running the dog around the house or up some stairs. A considerable number of puppies are born in the car on the way to the veterinarian. Most of these would probably have been delivered in the calm and quiet of home had the owners tried to induce straining themselves, thereby giving the puppies a better start in life and possibly also resulting in the whole litter being born without further intervention. Another means of induction of straining in the bitch with insufficient labor is by feathering of the dorsal vaginal wall. Feathering is accomplished by inserting two fingers into the vagina and pushing or "walking" with them against the dorsal vaginal wall, thus inducing an episode of straining (the Ferguson reflex). Feathering can also be effective in initiating labor after correction of the position or posture of a fetus. Nervous voluntary inhibition of labor due to psychologic stress may occur, mainly in a nervous primiparous animal. Reassurance by the owner or administration

of a low-dose tranquilizer may remove the inhibition.[21] Once the first fetus is born, parturition will usually proceed normally.

The bitch with complete primary uterine inertia is usually bright and alert, has a normal rectal temperature, and has no evidence of labor. The cervix is often dilated, and vaginal exploration is easy to perform owing to the presence of fetal fluids, but the fetus may be out of reach because of the flaccid uterus. Before initiation of medical treatment of uterine inertia, obstruction of the birth canal must be excluded.

Calcium solutions and oxytocin are the drugs of choice in cases of uterine inertia. Oxytocin has a direct action on the rate of calcium influx into the myometrial cell, essential for myometrial contraction. Many bitches do not respond to oxytocin alone but require prior administration of a calcium solution. Therefore some 10 minutes before the administration of oxytocin, 10% calcium borogluconate, 0.5 to 1.5 mL/kg body weight, should be given by slow intravenous infusion (1 mL/min) with careful monitoring of the heart rate. The calcium can also be administered subcutaneously, which eliminates the risk for arrhythmia but presents a small risk for granuloma formation at the injection site. Small breed bitches may be prone to hypoglycemia, particularly after prolonged straining. In such cases a dilute (10% to 20%) glucose solution can be added to the infusion or given intravenously in doses of 5 to 20 mL. The recommended dose of oxytocin for the bitch is 1 to 5 IU given intravenously or 2.5 to 10 IU intramuscularly, which can be repeated at 30-minute intervals. The response to treatment will be reduced with each repeated administration. Higher doses than recommended or too frequent administration may result in prolonged contracture of the myometrium, preventing fetal expulsion and impeding uteroplacental blood flow. The disadvantages of oxytocin administration include a tendency to cause premature induction of placental separation and cervical closure. If no response to treatment is seen after a second administration of oxytocin, the puppies should be delivered without further delay, either with the aid of obstetric forceps (if only one or two puppies remain and are within easy reach in the uterine corpus) or by cesarean section.

1660

1662

Figure 248-2 Algorithm defining the various maternal causes for dystocia.

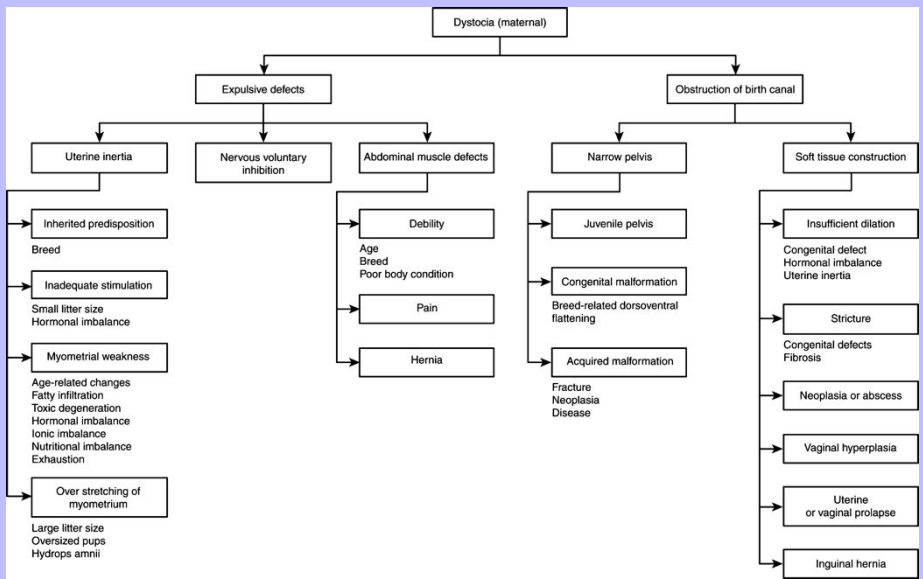


Figure 248-3 Algorithm defining the various fetal causes for dystocia.

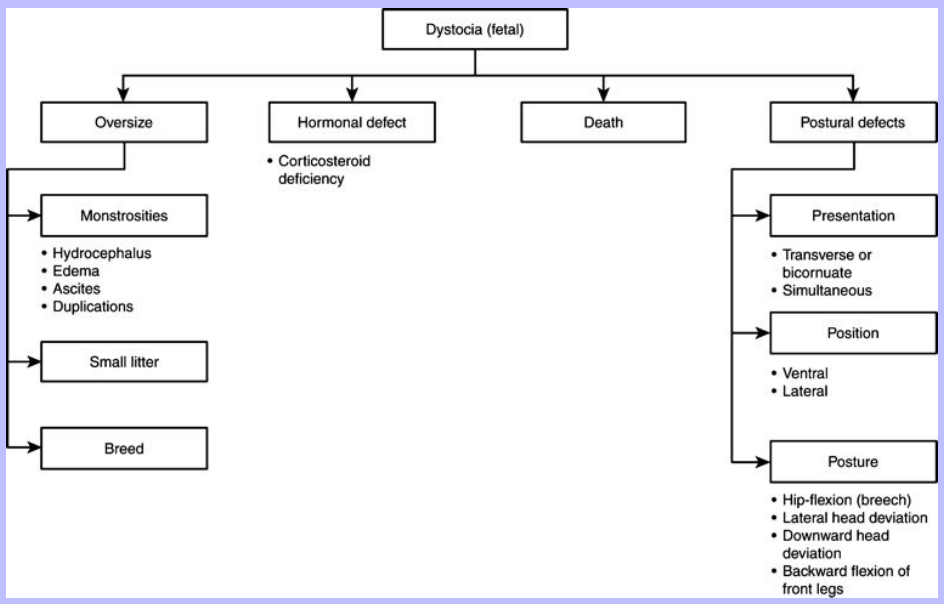

The long-acting ergotamines should never be used in connection with parturition. The treatment regimen includes the following:

- The owner runs with the bitch and feathers the vaginal vault.
- A 10% solution of calcium gluconate is given slowly intravenously while carefully checking the bitch's heart rate.
- The bitch is given 30 minutes to respond to treatment. If straining begins, the treatment can be repeated if necessary or continued with oxytocin.
- If the calcium infusion has no effect within 30 minutes, oxytocin is given intravenously or intramuscularly.
- The bitch again is given 30 minutes to respond to treatment. If straining begins, the treatment can be repeated if necessary, although each additional administration will elicit a weaker response.
- If nothing happens within 30 minutes, it is not likely that further treatment will be successful. The fetuses should be delivered, either by forceps, if only one or two fetuses remain and are within easy reach, or by cesarean section.

248.4.5.2 Obstruction of Birth Canal

Obstruction of the birth canal may be of maternal or fetal origin. Some maternal causes for obstruction include:

- Uterine torsion and uterine rupture. These are acute, life-threatening conditions that can occur during late pregnancy or at the time of parturition. Sometimes a few fetuses are born before parturition stops, and the condition of the bitch may quickly deteriorate. Surgery is always required, and a quick diagnosis essential for survival.

- Uterine inguinal herniation usually is detected around the fourth week of pregnancy as the fetal uterine enlargements are growing and the contour of the abdomen is markedly abnormal. Sometimes the early stages may be mistaken for mastitis of the rear mammary glands. The condition is corrected by surgery, whereby the uterine horns are repositioned and the herniation sutured. In cases with circulatory disturbance and advanced tissue damage, the uterus will have to be removed. 1662 1663

- Congenital malformations of the uterus (e.g., partial or complete aplasia or hypoplasia of one or both uterine horns or of the corpus uteri) or the cervix are rare causes of maternal obstructive dystocia. Symptoms depend on the character and degree of the malformation. In cases of unilateral aplasia of an entire uterine horn, small litter size may be the only sign. Retained fetuses behind partial occlusions require surgery, and the final diagnosis is usually made during the operation.

- Soft tissue abnormalities such as neoplasms, vaginal septa, or fibrosis of the birth canal may cause obstructive dystocia. The prepartum relaxation of the vagina will often allow the passage of fetuses. Vaginal septa may consist of remnants from the fetal Müllerian duct system. However, they can also occur secondary to vaginal trauma or infection and, if extensive, may prevent the passage of the fetuses. Often, however, they are not so extensive, and vaginal relaxation may allow the fetuses to pass. Cervical or vaginal fibrosis usually is secondary to trauma or inflammatory processes and in severe cases will cause dystocia. Surgical intervention may save the puppies. Tumors and septa formations may be removed; but in the case of fibrosis, surgery is seldom successful because of new scar tissue formation during the healing process.

- Narrow pelvic canal causing obstructive dystocia may result from previous pelvic fractures, immaturity, or congenital malformation of the pelvis. The normal canine pelvis usually has a vertical diameter greater than the horizontal. Congenitally narrow birth canals exist in some brachycephalic and terrier breeds; in addition, their fetuses have comparatively large heads and wide shoulders. When achondroplasia exists, as in the Scottish terrier, dorsoventral flattening of the pelvis modifies the normal pelvic inlet, which creates a fetal obstruction. In a study using indirect pelvimetry, significant differences were found between Scottish terrier bitches whelping normally compared with those with dystocia owing to a too narrow birth canal, confirming the dorsoflattening and also demonstrating a shortening of the pelvis in the bitches with dystocia. The weight of the puppies was the same in both groups.[17] Boston terrier bitches were also studied, and again a significantly greater inner pelvic height was found in the normally whelping bitches; however, in this breed the size of the puppies was also of importance because the weight of the pup was related with the size of its head. In the bulldog the large, deep chest and pronounced waist causes the gravid uterus to drop down. At parturition, the fetuses are therefore presented at a relatively acute angle to the pelvic inlet. Bulldogs sometimes also have slack abdominal musculature, leading to insufficient uterine contractions and abdominal straining to lift the fetus up into the pelvic cavity.

248.4.6 Fetal Causes of Dystocia

Fetal obstructions may be caused by malpresentations, malorientations, or oversized fetuses as well as monstrosities including hydrocephalus, edema, or various duplications (see Figure 248-3). Simply being

oversized is a cause for malpresentation. Fetal death may result in dystocia due to malpositioning or inadequate stimulation for parturition to begin. A healthy fetus is active during expulsion, extending its head and limbs, twisting, and rotating to get through. In most breeds the greatest bulk of the fetus lies in its abdominal cavity, whereas the bony parts (the head and the hips) are comparatively small. The limbs are short and flexible and rarely cause serious obstruction to delivery in the normal-sized fetus.

248.4.6.1 Oversized Fetuses

A puppy weighing 4% to 5% of the weight of the bitch is considered the upper limit for an uncomplicated birth. In the absence of monstrosities, oversized fetuses are often associated with small litter size. In breeds in which miniaturizing exists, great disparity in fetal size within litters may occur, with some greatly oversized individuals. In brachycephalic breeds like the Boston terrier, dystocia occurs from the combination of a flattened pelvic inlet and puppies having a large head. Obstructive dystocia was found to occur already at pup weights of 2.5% to 3.1% of the adult weight in these breeds.[18] In dystocia due to an oversized fetus, sometimes a portion of the fetus may protrude from the vulva. In anterior presentation the head may be born and the shoulders and chest cause obstruction, whereas in posterior presentation the hind limbs and hips may protrude.

248.4.6.2 Posterior Presentation

Posterior presentation is considered normal in dogs, occurring in 30% to 40% of fetal deliveries.[14,16,17] Posterior presentations have, however, been related both to higher pup mortality[17] and to a predisposition for dystocia, because mechanical dilation of the cervix may be inadequate, particularly where this involves the first fetus to be delivered. In addition, expulsion is rendered more difficult because the fetus is being delivered against the direction of its haircoat and because the fetal chest, instead of being compressed, becomes distended by the pressure from the abdominal organs through the diaphragm. Occasionally the fetus may have the elbows hooked around the pelvic brim, preventing further expulsion. Should the fetus become lodged in the pelvic canal, pressure on the umbilical vessels trapped between the fetal chest wall and maternal pelvic floor may cause hypoxia and reflex inhalation of fetal fluids.

248.4.6.3 Breech Presentation

Breech presentation (i.e., posterior presentation with hind legs flexed forward) can be a serious complication, especially in medium-and small-sized breeds. Vaginal exploration will reveal a tail tip, maybe the anus, and the bony structure of the pelvis of the fetus.

248.4.6.4 Lateral or Downward Deviation of the Head

These are two of the most common malpositionings in the dog. Lateral deviation is most common with long-necked breeds such as rough collies, whereas downward deviation is seen in brachycephalic breeds and long-headed breeds such as Sealyham and Scottish terriers. In lateral deviation, vaginal exploration will demonstrate just one front leg, the one contralateral to the direction of the deviation of the head (i.e., when the head is deviated to the left, the right front paw will be found and vice versa). When the animal has a downward deviation of the head, either both front legs and sometimes the nape of the neck of the fetus can be palpated, or both front legs may be flexed backwards and only the scull of the fetus be reached.

248.4.6.5 Backward Flexion of Front Legs

This condition is especially common when the fetus is weak or dead and is sometimes seen in combination with deviation of the head, especially downward. For bitches of the larger or even medium-sized breeds, it may be possible to deliver a puppy with one or both front legs flexed.

1663

1664

248.4.6.6 Transverse or Bicornual Presentation

Sometimes a fetus, instead of progressing from the uterine horn through the cervix to the vagina, will proceed into the contralateral uterine horn, possibly due to some obstruction. Another reason may be that the fetus was implanted close to the body of the uterus. These cases always require surgery, because no possibility for manual correction exists.

248.4.6.7 Two Fetuses Presented Simultaneously

Sometimes one fetus from each horn is presented at the same time, jamming the birth canal. When possible, if one is coming backwards, this one should be removed first, because it occupies more space.

248.4.6.8 Management of Fetal Malpresentations

If a fetus is present in the birth canal, manipulation by hand or by obstetric forceps may be attempted. In bitches of the giant breeds it may even be possible to insert one hand through the vagina into the uterus and thus extract the puppy. During natural birth the puppy will almost make a full somersault, emerging from the loop of the uterine horn, progressing upwards to pass through the pelvic canal, and then moving down through the long vestibulum of the bitch to reach the vulva placed some 5 to 15 cm below the level of the pelvic floor. Thus after the fetus is seized, a gentle traction in posteroventral direction is applied.

Fetal position must be assessed. If the fetus has advanced into and partly through the pelvic canal, it will create a characteristic bulge of the perineal region, below the tail. Easing the vulvar lips upward may reveal the amniotic sac and the position of the fetus. Vaginal exploration and radiographic examination will aid in making a diagnosis in the cases when the fetus has not advanced as far.

The narrowest part of the birth canal is within the rigid pelvic girdle. If external manipulation is to be attempted, the fetus that cannot be easily pulled out may have to be pushed forward to in front of the pelvic girdle, where corrections of its position or posture are easier to perform. This should be done between periods of straining of the bitch, never working against the uterine contractions. It should also be remembered that the widest part of the pelvic girdle usually is on the diagonal (see Figure 248-1); thus rotating the fetus 45 degrees may create sufficient room for passage. Generous application of obstetric lubricant (liquid paraffin, Vaseline®, or a sterile water-soluble lubricant) is helpful, especially if the bitch has been in second-stage labor for some time.

Depending on the position and posture of the fetus, a grip should be applied around its head and neck, from above or below whichever is most convenient, around its pelvis, or around the legs. Care should be taken because the neck and limbs of the fetus are easily torn when pulled. Correction of posture may be obtained by manipulation of the fetus through the abdominal wall with one hand and concurrent transvaginal manipulation with the other. A finger may be introduced into the mouth of the fetus to help correct a

downward deviation of the head. Should it be necessary to change the postures of the limbs, a finger should be inserted past the elbow or knee and the limb moved medially in under the fetus and corrected.

A gently applied alternating right-to-left traction of the puppy, gently rocking it back and forth or from side to side and possibly twisting it to a diagonal position within the pelvis, will help free the shoulders or the hips one at a time. A slight pressure applied over the perineal bulge may prevent the fetus from sliding back into the uterus again between strainings.

Obstetric forceps should only be used for assisted traction of a relatively oversized fetus when it is likely the rest of the puppies in the litter are smaller or when just one or two fetuses remain. The forceps is guided with a finger and never introduced further than to the uterine body because of the risk of getting part of the uterine wall within the grip, thereby causing serious damage. If the head of the fetus can be reached, the grip should be applied around the neck (Pålssons forceps) or across the cheeks. In posterior presentation the grip should be around the fetal pelvis. If the legs can be reached, the grip should be around those, not around the feet.

248.4.6.8.1 Outcome of obstetric treatment

A study[13] reporting on treatment outcome shows that digital manipulation, including forceps delivery, medical treatment for dystocia, or both, is successful in only 27.6% of the cases. Around 65% of bitches brought to the clinic because of dystocia thus end up having a cesarean section.

Fetal death increased from 5.8% in bitches brought in within 1 to 4.5 hours after the beginning of second-stage labor to 13.7% in the period between 5 to 24 hours. Overall fetal death was 22.3%.[13] Early diagnosis and prompt treatment is therefore crucial in reducing the puppy death rate in cases of dystocia.

248.4.6.9 Criteria for Cesarean Section

The indications for cesarean section include the following:

- Complete primary uterine inertia that does not respond to medical treatment
- Partial primary uterine inertia that is refractory to medical management
- Secondary uterine inertia with inadequate resumption of labor
- Abnormalities of the maternal pelvis or soft tissues of the birth canal
- Relative fetal oversize, if considered likely to be repeated in several fetuses
- Absolute oversize (single-puppy syndrome or fetal monstrosity)
- Excess or deficiency of fetal fluids
- Fetal malposition unamendable to manipulation
- Fetal death with putrefaction
- Toxemia of pregnancy and illness of the bitch

- Neglected dystocia
- Prophylactic (history of previous difficult deliveries)

Prophylactic cesarean section should be questioned on ethical grounds if it is performed to assist the propagation of a breed line that cannot reproduce successfully without intervention.

Once a decision has been made to deliver the litter by cesarean section, surgery should be carried out without delay. The bitch has often endured hours of more or less intensive labor and may be suffering from physical exhaustion, dehydration, acid-base disorders, hypotension, hypocalcemia, hypoglycemia, or a combination of these symptoms. The prognosis for both bitch and offspring is good if surgery is performed within 12 hours after the onset of second-stage labor; it continues to be fairly good for the bitch after 12 hours but guarded for the fetuses. If more than 24 hours have passed after the onset of second-stage labor, the entire litter is usually dead and further delay compromises the life of the bitch.

248.5 POSTPARTURIENT CONDITIONS

It is normal for the bitch to have a slightly elevated rectal temperature, up to 39.2° C (102.56° F), for a couple of days after parturition. It should, however, not exceed 39.5° C (103.1° F). Fever during this period usually emanates from conditions of the uterus or the mammary glands.

1664

1665

248.5.1 Perinatal Loss

Based on a number of surveys, pup losses up to weaning age appear to range between 10% and 35%[17,20,22] and averages around 12%.[22–24] More than 65% of pup mortality occurs at parturition and during the first week of life; few neonatal deaths occur after 3 weeks of age. Inbreeding is said to be associated with a high incidence of fetal and neonatal mortality. Breed differences in pup mortality patterns have been reported.[17] The principal cause of pup mortality has been attributed to fetal asphyxia, accounting for 42.5% of the total mortality. The majority of these pups (82.2%) died during whelping or in the first 24 hours after birth. The death of just over half of these pups could be directly attributed to dystocia. The remaining pups were compromised during what appeared to be a normal whelping.[17]

248.5.2 Uterine Disorders

248.5.2.1 Hemorrhage

Some hemorrhage from the genital tract after parturition is normal, but maternal blood loss should never exceed a scant drip from the vulva. True hemorrhage should be distinguished from normal vaginal postparturient discharge. Excessive hemorrhage after parturition may indicate uterine or vaginal tearing or vessel rupture or may be evidence of a coagulation defect. The hematocrit should be checked, remembering that 30% is normal for the bitch at term. Inspection of the vulva and vagina should be performed in an attempt to locate the source of the bleeding. Oxytocin can be administered to promote uterine involution and contraction of the uterine wall. In more severe cases of uterine hemorrhage, an exploratory laparotomy may be necessary. The bitch should be monitored closely for signs of impending shock, and blood transfusion may be required while attempting to determine the cause of hemorrhage.

248.5.2.2 Retained Placentas and Fetuses

Retained placentas in the bitch may cause severe problems, especially when accompanied by retained fetuses or infection. Clinical signs of retained placenta include a thick dark vaginal discharge. Retained fetuses can be identified by palpation or radiographic or ultrasonographic examination. The examination should also encompass the corpus uteri and the vagina in search for partly expelled fetuses or fetal membranes. A retained placenta is often palpable in the uterus, depending on the size of the bitch and degree of uterine involution. Extraction of retained tissue, by careful "milking" of the uterine horn or by using forceps, is sometimes possible. Treatment with 1 to 5 IU oxytocin per dog subcutaneously or intramuscularly two to four times daily for up to 3 days can help expulsion of retained placentas. The long-acting ergot alkaloids should not be used because they may cause closure of the cervix. Antibiotic treatment is advisable if the bitch is showing signs of illness.

248.5.2.3 Acute Metritis

Acute metritis is an ascending bacterial infection of the uterus in the immediate postpartum period. Dystocia, obstetric manipulation, retained fetuses or placental membranes, or parturition in an unsanitary environment predispose to metritis. Metritis may rarely occur after normal parturition, natural or artificial insemination, or an abortion. Infection usually ascends through an open cervix and is often caused by gram-negative bacteria. Clinical signs include fever, dehydration, depression, anorexia, poor lactation and mothering, and a purulent or sanguinopurulent vaginal discharge. A doughy enlarged uterus may be palpated abdominally. Abdominal radiographic or ultrasonographic examination (or both) is indicated to evaluate the uterine size and uterine contents. A vaginal culture is recommended. Vaginal cytology will show large numbers of degenerate neutrophils, red blood cells (RBCs), bacteria, and debris. The complete blood count (CBC) often shows leukocytosis with a left shift. Therapy consists of immediate administration of intravenous fluids and antibiotics and evacuation of uterine contents. The latter may be accomplished by administering oxytocin or $PGF_{2\alpha}$. One high-dose regimen exists for administration of $PGF_{2\alpha}$ (0.1 to 0.25 mg/kg subcutaneously once or twice daily for 3 to 8 days) and one low-dose regimen (0.025 to 0.05 mg/kg subcutaneously six to eight times daily for 2 to 3 days). The high-dose alternative may cause adverse reactions such as abdominal pain and increases in pulse rate, respiratory rate, and salivary secretions. These reactions appear within 10 minutes of administration and normally disappear again after 30 minutes to 1 hour. It should be remembered, however, that the prostaglandins are not licensed for use in dogs. In more severe cases, ovariohysterectomy (OHE) is the recommended treatment.

248.5.2.4 Subinvolution of Placental Sites

In the postparturient period it is normal for the bitch to have a serosanguineous vaginal discharge for 3 to 6 weeks. Normally the uterine involution is completed within 12 weeks after whelping. Subinvolution of placental sites is suspected if a sanguineous vaginal discharge persists for longer than 6 weeks (Figure 248-4). The cause of this condition is unknown, and the bitch often shows no symptoms of illness. Vaginal cytology shows predominantly RBCs, with syncytial trophoblast-like cells being a useful confirmatory finding. Subinvolution of placental sites almost exclusively affects the young, primiparous animal, and in the majority of cases resolves spontaneously, with the prognosis for future pregnancy being good. Because of increased risk of anemia, secondary bacterial infection, or rupture of the affected placental sites with subsequent peritonitis, the bitch should be monitored until the disorder resolves. OHE is indicated in rare cases of profound permanent bleeding or uterine infection.

248.5.2.5 Uterine Rupture

Uterine rupture should be considered a possible but uncommon cause of illness in the postparturient period. Uterine rupture can occur when prostaglandins or oxytocin have been administered for induction of abortion or treatment of pyometra, metritis, or dystocia. The condition may occur as a result of dystocia or during an apparently normal parturition or may be due to injury occurring in late pregnancy. The clinical signs of uterine rupture include abdominal pain and distention and a rapid deterioration of the condition of the bitch. The diagnosis is confirmed by exploratory laparotomy, and OHE is the usual treatment combined with intravenous fluids and antibiotic therapy.

248.5.2.6 Uterine Prolapse

Uterine prolapse is an uncommon complication during parturition. It occurs in primiparous and multiparous bitches. The prolapse usually occurs immediately or within a few hours after delivery of the last pup. The prolapse can be complete, with both uterine horns protruding from the vulva, or may be limited to the uterine body and one horn. Treatments include manual reposition, reposition by means of laparotomy, and amputation. OHE is usually performed.

248.5.2.7 Toxic Milk Syndrome

The toxic milk syndrome is poorly documented. Pathologic conditions in the uterus of the bitch may cause toxins to be excreted in the milk. Suckling offspring that are affected by toxic milk syndrome become vocal and uncomfortable. Other signs are diarrhea, salivation, bloating, and a reddened anus. Treatment consists of removing the pups from the bitch and the administration of fluid therapy and oral glucose until bloating resolves. If the bitch is successfully treated for the uterine condition, the litter can be returned after 24 to 48 hours, otherwise hand rearing is necessary.

Figure 248-4 ***A***, Subinvolution of the placental sites. In the unopened left uterine horn the typical oval swellings of the placental areas can be observed. In the opened horn, the placentation zones and the hemorrhage emanating from those areas can be seen. ***B***, A hystographic picture of a bitch with subinvolution of the placental sites, 4 months after whelping. The placentation zones are seen as darker areas. Normal uterine involution is completed within 12 weeks in the bitch.

248.5.3 Mammary Gland Disorders

248.5.3.1 Agalactia

Agalactia, or absence of milk after parturition, may be due to a failure of milk production or milk letdown. True agalactia, failure of milk production, is uncommon but may occur repeatedly in some bitches. More commonly it may be observed after premature parturitions or cesarean sections. Treatment with metoclopramide 1 to 5 mg/kg subcutaneously or per orally every 6 to 8 hours for a maximum of 5 days may promote prolactin release and milk production in these cases. Failure of milk letdown may occur as a consequence of excessive secretion of epinephrine, resulting from fright or pain, which has a blocking effect upon the release of oxytocin. Oxytocin 0.5 to 2.0 IU per dose can be administered repeatedly for a

few days until milk flow has been established. Primiparous, nervous, or confused bitches may experience temporary agalactia. Reassurance by the owner and administration of low doses of acepromazine orally may help the bitch to settle down, and subsequent suckling by the puppies will enhance milk flow. Other causes of agalactia are physical exhaustion, undernourishment, shock, mastitis, metritis, systemic infections, and endocrine imbalances.

248.5.3.2 Galactostasis

Milk stasis (i.e., galactostasis) causes enlarged and edematous mammary glands that are firm and warm to the touch. The bitch shows signs of discomfort and pain and fails to let down milk. The condition should be differentiated from mastitis and agalactia. The cause is unknown in dogs, but it usually involves the two most caudal pairs of mammae in bitches with a high milk production, with few puppies, or with both. It can also occur in glands with malformed teats, which the offspring avoid suckling. Another cause can be that nursing comes to an abrupt end owing to death of the litter or sudden weaning. To relieve mammary congestion the owner can apply gentle massage and warm-water compresses to the mammary glands or perform careful milking to relieve some of the pressure. Sometimes it helps to put more aggressively nursing neonates to the bitch. Treatment includes reducing food intake and the administration of a mild diuretic. Neglected galactostasis may lead to mastitis or involution of the mammary gland. Cabergoline (Galastop vet.), a dopamine agonist, at 2.5 to 5 µg/kg/day orally for 4 to 6 days, reduces prolactin secretion and thereby lactation. The use of dopamine agonists should be restricted to bitches that have either lost their litter or have a litter old enough to be weaned.

248.5.3.3 Acute Mastitis

Acute mastitis in the bitch occurs from hematogenously spread bacterial infections or from bacteria ascending through the teat orifices. Predisposing factors include mammary gland congestion, trauma, and poor sanitary conditions. The mammary glands become hot, painful, and enlarged; the milk shows increased viscosity and changes in color from yellow to brown, depending on the amount of blood and purulent exudate present. Clinical signs include fever, anorexia, and depression in the bitch. The offspring may be restless and crying. Milk cytology reveals the presence of degenerate neutrophils, RBCs, and bacteria. Culture of the milk often shows growth of *Staphylococcus* spp., *Streptococcus* spp., or *Escherichia coli*. Treatment consists of adequate antibiotics, application of warm-water compresses, and massage of mammary glands. If abscessation of the glands occurs, surgical débridement and drainage is essential. Untreated acute mastitis may result in gangrenous mastitis and septic shock. Depending on the severity of the condition, the litter may stay with the bitch or has to be separated and hand reared.

1666

1667

248.5.4 Miscellaneous Disorders

248.5.4.1 Puerperal Tetany

An acute decrease in extracellular calcium concentration is the cause of puerperal tetany (eclampsia). Eclampsia occurs most commonly in dogs of the small breeds, usually within the first 21 days after whelping, but occasionally during late pregnancy or at parturition. Early signs are restlessness, panting, pacing, whining, salivation, tremors, and stiffness. The symptoms aggravate to clonic-tonic muscle spasms, fever, tachycardia, miosis, seizures, and death. Treatment must be instigated immediately and consists of slow intravenous infusion of a 10% calcium borogluconate solution. The dose required varies depending on the degree of hypocalcemia and the size of the bitch. Careful cardiac monitoring for bradycardia and

arrhythmias is important. If arrhythmia or vomiting occurs, the infusion must be temporarily halted and then, if necessary, resumed at a slower rate. Because hypoglycemia may follow hypocalcemia, the intravenous administration of a 10% dextrose solution is recommended. The puppies should be removed from the bitch and hand fed a canine milk replacer for 24 hours. If the litter is 4 weeks old or more, it is advisable to wean them. Oral supplementation of the lactating bitch having experienced eclampsia with calcium carbonate at 100 mg/kg body weight per day, divided with meals, and vitamin D is recommended. Prophylactic calcium treatment during the course of pregnancy of bitches expected to develop eclampsia probably is contraindicated, because it may cause a disturbance of the calcium homeostasis.

248.5.4.2 Disturbances in Maternal Behavior

Maternal behavior involves hereditary factors, several hormones (e.g., estrogens, progesterone, oxytocin, and prolactin), previous experiences as a mother, and the stimulus of the neonate. Good maternal behavior includes nest building, nursing, and protecting. The period during which the bitch will form a bond with a pup is probably less than 24 hours. The bitch should spend most of the time with the litter for at least the first 2 weeks. Most bitches have strong maternal instincts, but their behavior depends strongly upon their hormonal balance, general health, and the environment. In some breeds a higher occurrence of bad mothering exists, and in other species several genes for maternal behavior have been identified. Sublimation (i.e., close emotional attachment to a human) may cause problems at parturition, when the bitch may manifest panic and reject her pups.[21] On the contrary, a bitch may resent human intervention, not accepting assisted birthing and cesarean-delivered offspring, and may sometimes even kill them. Major disturbing factors during and after parturition, mental instability, or pain may cause the mother to kill her neonates. Hypocalcemia should always be ruled out in cases of aggression in lactating bitches. Good health, quiet and familiar surroundings, and most important of all, presence of her young will promote normal maternal behavior.

249 CHAPTER • 249 Early Spay and Neuter

Margaret V. Root Kustritz

Prepuberal gonadectomy is castration or ovariohysterectomy of puppies or kittens 6 to 14 weeks of age. Performance of neutering of dogs and cats at the more traditional age of 6 months usually also occurs before puberty, so the term *early spay and neuter* is perhaps more correct. Early spay and neuter surgeries have been performed at humane organizations and universities in at least 17 states for as many as 13 years. The procedure is approved by many major veterinary professional and humane organizations, including the American Veterinary Medical Association.[1]

Surgical neutering of young puppies and kittens is of greatest advantage to humane organizations, because it circumvents the problem of noncompliance by adopters with spay and neuter agreements after adoption. It also permits placement of neutered animals while they are still young enough to benefit from socialization in the new home. Breeders may also benefit from the procedure, which allows placement of neutered pet-quality puppies and kittens while still young, precluding indiscriminate breeding of animals that do not meet the breed standard or that carry hereditary disorders.

In one survey, 57% of humane shelters surveyed could not provide young puppies and kittens that already had been neutered because of unavailability of a veterinarian to perform the surgeries.[2] In 1998 only 48% of 29 North American veterinary colleges responding to a survey reported teaching early spay and neuter surgeries to their students despite 90% having a working relationship with a local humane organization.[2] Students polled at a university after completing a rotation in which early spay and neuter surgeries were performed stated that performance of early spay and neuter surgeries increased their confidence in performing pediatric surgery and anesthesia in general.[3]

Pediatric anesthesia is complicated by the immature physiology and small body mass of the animals.[4] Hypothermia occurs readily in puppies and kittens. Fluids used for surgical preparation should be warm and water based as opposed to alcohol based. The animal should be maintained on a circulating warm-water pad, and anesthesia and surgery time should be minimized to prevent heat loss. Intravenous fluids to be administered intraoperatively also should be warmed.

Hypoglycemia occurs more readily in pediatric than in adult animals because of reduced glycogen stores in skeletal muscle and liver and slower rates of hepatic gluconeogenesis and glycogenolysis. Pediatric animals should be fasted for no more than 3 to 4 hours before anesthesia is induced. Dextrose may be provided in the intravenous fluids intraoperatively.

Pharmacokinetics of drugs administered are altered by immature pediatric renal and hepatic physiology, which do not approach adult levels until the animal is 12 to 14 weeks of age.[4] The overall effect of these physiologic changes is increased availability of anesthetic agents for a longer period of time due to decreased metabolization and slower rate of excretion; drug doses may need to be reduced in pediatric animals.

Anesthetic equipment should be of a size that minimizes resistance and dead space.[5,6] Masks should be tight fitting. Monitoring of anesthesia involves close observation of heart and respiratory rates. Pediatric animals cannot respond to hypoxia with increased stroke volume and do not respond readily to increased concentrations of carbon dioxide in blood with an increase in respiratory rate.[7]

Several anesthetic protocols for early spay and neuter of puppies and kittens have been reported. The optimal reported protocols, defined as those that minimized induction and recovery times and provided the smoothest induction and recovery and best depth of sedation, are listed in Table 249-1.[5,6]

Surgical procedures are as in older animals.[5,8,9] This is an elective procedure and should only be performed on those animals that are in good health, are free of internal and external parasites, and are vaccinated. General principles of surgery on pediatric animals should be observed. These include gentle tissue handling, decreasing surgery time to minimize intraoperative hypothermia, and maintaining meticulous hemostasis.

Castration in puppies is performed as in adult dogs. Both testes are removed through a single prescrotal incision. Both a *closed technique*, in which the tunic containing the spermatic cord and vessels are left intact, and an *open technique*, in which the tunic is opened, have been described.[5,9] Fine absorbable suture or hemostatic clips may be used for ligation of the spermatic cord and vessels. Closure is routine. Either subcuticular closure with absorbable suture or external interrupted or continuous nonabsorbable sutures may be used; external skin sutures have not been reported to bother puppies castrated prepuberally unless they are too tight.[9] Some reports exist of tissue glue used for skin closure after early spay and neuter surgeries, but this is not reported to work well in puppies.

Table • 249-1 Optimal Anesthetic Regimens for Early Spay and Neuter Surgeries in Puppies and Kittens*

	PUPPIES		KITTENS	
Males	Premed	Atropine (0.04 mg/kg IM) +oxymorphone (0.22 mg/kg IM)	Premed	—
	Induction	Propofol (6.5 mg/kg IV)	Induction	Tiletamine/zolazepam (11 mg/kg IM)
	Inhalant	Isoflurane as needed	Inhalant	Isoflurane as needed
Females	Premed	Atropine (0.04 mg/kg IM) +oxymorphone (0.11 mg/kg IV)	Premed	—
	Induction	Propofol (4.3 mg/kg IV)	Induction	Ketamine HCl (11 mg/kg IM) +midazolam (0.22 mg/kg IM)
	Inhalant	Isoflurane	Inhalant	Isoflurane

* From Faggella AM, Aronsohn MG: Evaluation of anesthetic protocols for neutering 6-to 14-week-old pups. J Am Vet Med Assoc 205:308–314, 1994; Faggella AM, Aronsohn MG: Anesthetic techniques for neutering 6-to 14-week-old kittens. J Am Vet Med Assoc 202:56–62, 1993.

Castration in kittens is performed as in adult cats.[6] Bilateral scrotal incisions are made. Both *closed techniques*, in which the spermatic cord and vessels within the tunic were either ligated or tied on itself, and an *open technique*, in which the spermatic cord and vessels were tied to each other, have been described. The scrotal incisions are left open to heal by second intention.

Ovariohysterectomy of puppies and kittens is as in adult animals. Serous fluid in the abdominal cavity is a not infrequent finding and is not associated with any known pathology.[5,8] Use of ovariohysterectomy (Snook) hooks is not recommended.[9] Carmalt clamps, with ridges perpendicular to the tissue enclosed within them, may be preferred to mosquito clamps for compression of the small ovarian vessels and uterine body.[7] Fine absorbable suture material or hemostatic clips may be used for ligation of the ovarian vessels and uterine body. Closure is routine. Subcuticular or external sutures may be used for closure of the skin.

Surgery time should be shorter for early spay and neuter surgeries than for similar surgery in older animals.[10] The animals recover quickly from anesthesia and should be fed a small meal as soon as possible to prevent hypoglycemia. Postoperative pain can be controlled by administration of butorphanol (0.11 to 0.22 mg/kg intravenously, intramuscularly, or subcutaneously);[10] most animals do not require postoperative pain management. External skin sutures can be removed in 10 to 14 days.

It is recommended that all puppies and kittens gonadectomized prior to 16 weeks of age be tattooed to prevent unnecessary surgical exploration to verify intact status later in life. Tattoos are recommended to be 1/2 to 3/4 inches in diameter, and should be placed in the prepubic area of females and the inguinal area of males; the preferred figure is the “male” or “female” symbol with an *x* across it (Figure 249-1).

A growing body of veterinary literature supports the safety of early spay and neuter surgeries. Short-and long-term complications hypothesized to occur include increased anesthetic and surgical morbidity and mortality, increased prevalence of infectious disease, obesity, stunting of growth, increased incidence of feline lower urinary tract disease, behavioral problems, and estrogen-responsive urinary incontinence. 1668 1669

Figure 249-1 Tattoo symbols recommended for placement in the prepubic area of female puppies and kittens and inguinal area of male puppies and kittens after early spay and neuter.

Short-term complications of anesthesia and surgery do not occur more commonly in animals neutered when young compared with those neutered when older. One study evaluating short-term effects of ovariohysterectomy and castration in 1213 dogs and 775 cats on which surgery was performed at less than 12 weeks, 12 to 24 weeks, or more than 24 weeks of age demonstrated that the short-term complication rate was highest in the group neutered at more than 24 weeks of age.[10]

Long-term complications of neutering also are not more common in animals undergoing early spay or neuter than in those animals neutered at more traditional ages, with the possible exception of predisposition to infectious disease in puppies.[11,12] In one study, incidence of parvovirus was higher in dogs neutered at less than 24 weeks of age compared with those neutered at more than 24 weeks of age.[12] This may have been due to the shelter from which the dogs originated, which had an overall higher incidence of parvovirus in young dogs than the other shelters in that study.

Obesity is a multifactorial problem. Retrospective studies have identified neutering as a risk factor for development of obesity. However, a study in dogs did not demonstrate an increase in body weight, food intake, or depth of back fat in those animals gonadectomized either at 7 weeks or 7 months of age, compared with those left intact.[13] That study was concluded when the animals were 15 months of age; predisposition to obesity may have become evident in the neutered animals at an older age. In cats, those neutered at either 7 weeks or 7 months of age had higher body weights and body condition scores and a larger falciform fat pad than did those left intact when evaluated at 24 months of age.[14,15] Metabolic rate has been demonstrated to be decreased in gonadectomized cats, regardless of age at time of surgery.[16]

Stunting of growth does not occur in animals gonadectomized when quite young. Closure of physeal plates is delayed in puppies and kittens gonadectomized at any time prior to puberty with subsequent increase in bone length.[13,14,17] Some question whether the delay in physeal closure may predispose these animals to growth plate fractures; no such correlation has been demonstrated.[18]

Feline lower urinary tract disease (FLUTD) has not been demonstrated to be more prevalent in cats gonadectomized when young. Urethral diameter is not significantly smaller or larger in male or female cats gonadectomized at either 7 weeks or 7 months of age, compared with intact cats at 22 to 24 months of age.[14,19]

Behavior problems have not been demonstrated to be more prevalent in animals gonadectomized when quite young. In addition, these animals are not less likely to be retained in homes after adoption than animals gonadectomized when older.[11,12,20] Service dogs neutered at 7 weeks of age are equally likely as dogs neutered at 7 months of age to be successfully trained and placed.[21]

Estrogen-responsive urinary incontinence has not been demonstrated to occur more commonly in animals gonadectomized when young. Estrogen-responsive urinary incontinence is, in fact, less commonly seen within 3 years of surgery in female dogs ovariohysterectomized before their first estrus than in female dogs ovariohysterectomized after their first estrus, with incidences of 9.7% and 20.1%, respectively.[22,23]

Early spay and neuter surgeries are safe and easy to perform. Performance of early spay and neuter surgeries allows veterinarians to sharpen their general skills regarding pediatric anesthesia and surgery and to provide a service to the humane organizations in their community and to the community at large.

250 CHAPTER • 250 Contraception and Pregnancy Termination in the Dog and Cat

Bruce E. Eilts

Contraception, or the prevention of pregnancy or estrus, is one of the most frequent requests made to veterinarians. Most often that request is for ovariohysterectomy (OHE), or spay, in the female or neutering (castration) in the male, which results in permanent sterilization. In addition to OHE, a permanent sterilization method is ovariectomy. Temporary estrus prevention has been achieved using several different drugs such as megestrol acetate, mibolerone, and testosterone. Immunologic methods to induce permanent or temporary sterility have been investigated but are not yet perfected. Often a client will request that an unwanted pregnancy be terminated. Pharmaceuticals such as estrogens, prostaglandin, prolactin inhibitors, dexamethasone, antiprogestogens, or combinations thereof have been used successfully in clinical situations to terminate pregnancy (Table 250-1). This chapter will present the most common techniques and drugs, including drug availability and drug cost at the time of writing, that are readily available. Techniques using drugs that are not available or in formulations not readily available in the United States will not be presented.

250.1 CANINE

250.1.1 Permanent Sterilization

250.1.1.1 Female

The most common contraceptive techniques in the dog are OHE for the female and neutering for the male. Advantages of OHE include permanent sterilization and prevention of estrual behavior, no remaining reproductive tract to incur future pathology, reduced incidence of mammary neoplasia in females, and decreased incidence of some prostatic disease in the male. Disadvantages include permanent sterilization, potential anesthetic complications (4.1% during OHE[1]), intra-and postoperative surgical complications

(7.3% for OHE[2]), pathology of reproductive tract remnants, urinary incontinence in the female, and obesity. Clients should be advised about side effects such as obesity and urinary incontinence. Although more females become obese after surgical sterilization than males, the causes of obesity are many and cannot be attributed solely to gonadectomy. Urinary incontinence exacerbated by low estrogen is a common side effect of gonadectomy in the bitch. The exact cause is unknown. The advantages and disadvantages of early spay and neuter are covered in Chapter 249. Although OHE is the most common technique used for permanent female sterilization in the United States, it has been shown that the long-term side effects associated with only performing ovariectomy are no different than when OHE is performed.[3,4] The advantages of performing ovariectomy include shorter surgery time, a smaller incision, and less abdominal trauma. Perhaps North American veterinarians should contemplate the advantages of ovariectomy over OHE. Tubal ligation, although rendering a female sterile, will not alleviate estrus and its associated unwanted behavior or reduce the incidence of mammary neoplasia.

250.1.1.2 Male

Neutering males is the most common technique available to consistently render males permanently sterile. Performing a vasectomy is uncommon. An attempt at intratesticular injections of glycerol to render males permanently sterile was not successful.[5] An intratesticular injection of zinc gluconate neutralized with arginine is now marketed as Neutersol. The company claims 99.6% effectiveness (with the need for anesthesia in only about 24% of dogs) when administered to puppies 2 to 10 months of age.[6]

250.2 TEMPORARY CONTRACEPTIVE TECHNIQUES

Before temporary contraceptive drugs are used, the client should be advised that only valuable breeding dogs should be left reproductively intact. Most dogs should have gonadectomies performed to sterilize them and remove sexual behavior. The most commonly available drugs to prevent estrus or pregnancy are megestrol acetate, mibolerone, and testosterone. Megestrol acetate has been marketed as Ovaban. To prevent estrus, the clinician should administer 0.5 mg/kg for 32 days starting at least 1 week before the next anticipated estrous cycle. The manufacturer approves a maximum of 32 days treatment. The next estrus will be in 4 to 5 months if estrus was imminent. If given during diestrus (for example, the client did not know the estrual stage) the next estrous cycle will occur at the regularly anticipated time. To stop estrus when the bitch is in the first 3 days of proestrus, the manufacturer recommends administering 2 mg/kg/day for 8 days. The next estrous cycle will be 4 to 6 weeks earlier than it normally would have been. It is recommended that the drug not be used during the first estrous cycle and that not more than two consecutive estrous cycles be suppressed. Side effects include increased appetite, weight gain, and (uncommonly) pyometra or mammary neoplasia. However, the drug is contraindicated in bitches with mammary neoplasia, diabetes mellitus, liver disease, uterine disease, or pregnancy. Apparently, it has no effect on post-treatment fertility. Ironically, the drug is not approved for breeding bitches.

Mibolerone was marketed as Cheque drops and is an androgen that blocks LH release, therefore preventing estrus. It is advised not to administer it before the first estrous cycle, because it will cause premature physeal closure. Treatment must be started at least 30 days before the next anticipated estrous cycle at an oral dose of 30 µg/day for dogs 0.5 to 12 kg, 60 µg/day for dogs 12 to 30 kg, 120 µg/day for dogs 25 to 50 kg, and 120 µg/day for dogs greater than 50 kg or German shepherd dogs. The manufacturer has approved administration for a maximum of 24 months, but the drug has been administered experimentally as long as 43 months without apparently causing problems. The next estrous cycle after stopping treatment will reportedly occur in 7 to 200 days (i.e., unpredictable) with normal fertility. If pregnancy does occur during treatment, any female pups will be masculinized. Side effects of mibolereone include clitoral hypertrophy, vaginal discharge, vaginitis,

aggressiveness, anal gland inspissations, musky body odor, and epiphora. It is also not recommended for breeding bitches.

Many Greyhound breeders may use testosterone to suppress estrus. Orally, methyl testosterone at 5 mg/wk (or divided, two times/wk) or parenteral testosterone propionate at a dose of 25 mg intramuscularly in the pectorals every 2 weeks prevents estrus. Clitoral hypertrophy or vaginal discharge may be side effects.

Many experimental methods such as antibody formation against GnRH[7] to prevent estrus or antibody formation against conception specific zona pellucida antigens[8] have been investigated; however, none have been consistently successful and none have been marketed.

Nothing that is effective for causing temporary infertility in the male is available. However, administration of leuprolide acetate (a GnRH agonist that down-regulates LH and therefore lowers testosterone concentrations) at a single dose of 1.0 mg/kg subcutaneously suppressed sperm production in 8 weeks and then persisted for 6 weeks.[9] The effects did reverse, leaving the hope that a drug may be available to cause temporary sterility in males.

250.3 PREGNANCY TERMINATION

250.3.1 Bitch

Only valued breeding animals should have pregnancy terminated in an effort to preserve future fertility. All other dogs should have an OHE performed to end the pregnancy. Drugs that can be administered during estrus to prevent pregnancy include estrogens and tamoxifen. If a request for pregnancy termination is made for a valued breeding animal, it must be decided if the bitch was actually in estrus and mated. A vaginal cytology examination will quickly determine if the bitch is in estrus. If the vaginal cytology slide is 90% to 100% cornified, the bitch is in estrus; and if the vaginal cytology slide does not contain cornified cells, the bitch is not in estrus (the bitch may have progressed into diestrus). Mating can be confirmed by the presence of sperm cells in the vaginal cytology; however, if no sperm cells are present in the vaginal cytology it cannot be assumed that the bitch was not mated. Sperm cells normally are not evident more than 24 hours after mating when doing routine vaginal cytology examinations. All bitches mated within 24 hours of obtaining a vaginal smear had sperm heads in the sample, and 75% that were mated within 48 hours had sperm heads when the vaginal cytology was prepared in the following manner.[10] A cotton swab moistened with saline is placed in the vagina for 1 minute, and then the tip of the swab is placed in a small tube containing 0.5 mL saline for 10 minutes. After 10 minutes the swab tip is squeezed dry into the tube and the fluid in the tube is centrifuged at 2000 × g for 10 minutes. The sediment is then stained using the same technique as a vaginal cytology.

1671

1672

Few alternatives exist if the client insists on a therapeutic procedure being performed when the bitch is in estrus before a pregnancy examination is performed. The only true mismate drugs available for this time period are the estrogens. The estrogens commonly used for mismate include estradiol cypionate (ECP), estradiol benzoate, and diethylstilbestrol (DES). The administration of DES is not effective as a mismate therapy.[11] Estradiol benzoate when administered at 0.01 mg/kg intramuscularly at 3 and 5 days (and occasionally 7 days) after mating in 358 bitches resulted in 16 (4.5%) of the bitches actually whelping.[12] None of the bitches had bone marrow aplasia reported, but there was a 7.3% incidence of pyometra reported (the "normal" incidence was reported to be 2% to 10% in the study).[12] Using ECP at a dose of 44 µg/kg one time during estrus resulted in no (0/4) bitches becoming pregnant, no pyometras, and no evidence of aplastic

anemia at 25 days after treatment.[11] Estrogens must only be used during cytologic estrus and the owner must be warned of potential side effects. If estrogens are administered during diestrus by mistake, or because it is assumed that one must wait 3 to 5 days after mating for administration, then the potential for inducing a pyometra rises considerably.[11] Reports of infertility after estrogen administration[13] are not documented, and in practice situations it is common to see a bitch become pregnant again during the next estrus.

The only other drug that can be used at the time of mismate presentation is tamoxifen citrate (Taxol, Bristol-Meyers, Squibb, New York, NY.). Tamoxifen citrate is normally considered to be an antiestrogen, but in dogs it has estrogenic activity. It has been administered at a dose of 1 mg/kg orally twice a day for 10 days starting either in proestrus, estrus, or the second, fifteenth, and thirtieth days of diestrus.[14] The drug had a 100% (12/12) efficacy for preventing pregnancy when administration began before the fifteenth day of diestrus, but when administered on the fifteenth day of diestrus or later it was not effective at preventing pregnancy. Side effects of the drug included pyometra, endometritis, and cystic ovaries when administered during all stages of the estrous cycle except early diestrus. Half (2/4) of the bitches receiving the drug during proestrus developed pyometra.[14] Because of the poor efficacy and side effects, tamoxifen citrate has not been widely used or accepted as a mismate drug in the dog.

If the client decides to pursue alternative therapies other than OHE or estrogens, it is important to have a pregnancy examination performed before instituting therapy, because 38% of bitches presented for elective pregnancy termination may not actually be pregnant.[15] The pregnancy examination should be performed at least 30 to 40 days after the possible breeding to minimize a false-negative diagnosis caused by an error in calculating the gestation duration from a mating that occurred early in estrus. Pregnancy diagnosis with ultrasound is reliable 25 days after the LH peak (19 days after the first day of diestrus). If a bitch is truly not pregnant, the expense, side effects, and any potential risks associated with pregnancy termination therapy can be avoided (albeit the expense of the pregnancy examination will be incurred). If the bitch is pregnant, the owners may elect to allow the bitch to have that litter and avoid any complications associated with pregnancy termination.

The most common therapies to terminate pregnancy rely on luteal demise, because the bitch requires an ovarian luteal progesterone source to maintain pregnancy. Luteolysis results in a decline in serum progesterone and when serum progesterone drops below 2 ng/mL for 24 hours, abortion occurs.[15] Many clinicians[15–18] have shown prostaglandins to be luteolytic in the bitch. The most common prostaglandin is the natural prostaglandin ($PGF_{2\alpha}$; Lutalyse, Pfizer, New York, NY). A single dose of prostaglandin will not result in luteolysis in the dog. Side effects of prostaglandin therapy include vomiting and diarrhea, but these only last about 30 minutes and tend to wane as the treatment protocol continues. However, it is recommended by some authors that bitches should be hospitalized for the duration of the treatment[19] or for at least 30 minutes after each treatment. To minimize caloric loss it is best to feed the bitches at least 1 hour after treatment so that the food is not vomited and lost on a daily basis. The natural $PGF_{2\alpha}$ is given at a dose of 0.1 to 0.25 mg/kg administered subcutaneously two to three times a day. A protocol found to have the fewest side effects is $PGF_{2\alpha}$ administered at a dose of 0.1 mg/kg subcutaneously every 8 hours for 2 days and then 0.2 mg/kg subcutaneously every 8 hours until abortion is complete.[15] Abortion is usually complete within 9 days,[15] but some bitches will abort fetuses and still have live fetuses after 9 days. It is extremely important to continue the treatments until abortion is complete and to use ultrasound examination to ensure that all the fetuses are expelled. Bitches have had normal litters after abortion with $PGF_{2\alpha}$.[19] The main drawbacks to using $PGF_{2\alpha}$ are the side effects and the duration of treatment. Prostaglandins have not been approved for inducing abortion in the bitch, so it is important to obtain client consent and forewarn them of the potential complications,

prolonged treatments, and need for multiple abdominal ultrasound examinations that need to be performed. Because of the side effects of the natural prostaglandins, potent synthetic prostaglandins, with fewer side effects, were developed.

Synthetic prostaglandins have also been used to induce abortion in the bitch. Synthetic prostaglandins available for the bovine include cloprostenol, fluprostenol, and alfaprostol. These synthetic prostaglandins have a much greater affinity for the prostaglandin receptors and have a longer half-life than natural prostaglandins. The synthetic prostaglandins also cause fewer smooth muscle contractions, therefore reducing side effects. It is important to note that the dose of the synthetic prostaglandins is much lower than that of the natural prostaglandin and that an error in dose calculation may be fatal. Cloprostenol has been used at a dose of 1 to 2.5 µg/kg subcutaneously once daily for 4 to 5 days and was 100% effective at inducing abortion after a 4 to 7-day treatment regimen.[20] The once-daily treatments of cloprostenol provide an advantage over treatments with natural prostaglandin, which are required every 8 hours. At the low dose of 1 µg/kg, the side effects of cloprostenol were noted to be minimal to none.[20]

In an attempt to alleviate any side effects associated with prostaglandin administration, other drugs have been added to the treatment regime. These include atropine sulphate at a dose of 0.025 mg/kg, prifinium bromide at a dose of 0.1 mL/kg, and metopimazine at a subcutaneous dose of 0.5 mg/kg.[21] Administration 15 minutes before a 2.5 µ/kg dose of cloprostenol given every 48 hours for three doses prevented side effects in 58% (39/67) of the bitches.[21] After one cloprostenol treatment, 53 of the 67 bitches had aborted, and after a second treatment 2 days later, 62 of the 67 bitches had aborted.

Other drugs that cause serum progesterone to decline are the dopaminergic drugs, which are prolactin inhibitors. Because prolactin is luteotropic during the second half of gestation,[22] lowering the prolactin concentration will cause luteal demise and result in a pregnancy loss. Prolactin inhibitors currently available include bromocriptine (Parlodel, Sandaz, Bloomfield, CO) and cabergoline (Dostinex, Pfizer, New York, NY).

1672
1673

Bromocriptine administered orally at a dose of 62.5 µg/kg twice daily to dogs at 43 to 45 days postovulation resulted in only two of four bitches aborting.[23] Side effects included two episodes of emesis in three of the bitches approximately 3 hours after treatment. Loose stools were also noted. Bromocriptine tabs can be crushed and dissolved in oil to ease dosing (because the compound is inactivated by water). Bromocriptine as a sole abortifacient does not appear to be a good choice in the bitch. It is more commonly used in combination with a prostaglandin product.

Cabergoline administered after 40 days of gestation at 60 µg orally once daily, given to a 32 kg German shepherd dog, resulted in abortion after 7 days with no side effects.[24] In contrast to Europe, only an oral 0.5 mg tablet of cabergoline is available in the United States. Cabergoline may be difficult to administer because the tablets are 0.5 mg and the dose for a 10 kg dog is only 0.05 mg. An oral solution, much like that done with bromocriptine, could be formulated. Expense may be a factor with this drug.

250.4 COMBINED STUDIES

In an effort to reduce the side effects and increase the efficacy of prostaglandins and prolactin inhibitors, a combination of the two has been used.[25] Cloprostenol at 1.0 or 2.5 µg/kg/day injected subcutaneously in combination with cabergoline at a dose of 1.65 µg/kg/day subcutaneously daily for 5 days from midgestation was 100% effective (5/5), and side effects were less severe than with cloprostenol alone. In the group treated with the low dose, no adverse side effects were noted.[25]

Oral cabergoline at a dose of 5 μg/kg/day given until 2 days after fetal death (mean: 9 days) combined with cloprostenol at a dose of 1 μ/kg every other day until fetal death (mean: 3 injections) starting at 25 days after the LH peak resulted in 100% (5/5) of bitches resorbing fetuses.[26] Fetal death was documented with ultrasound. There were no side effects of treatment when the cabergoline was administered 1 hour after the cloprostenol, but the bitches did have a serosanguineous discharge that lasted an average of 16 days. Combinations of cabergoline, bromocriptine, and cloprostenol have been used[26] and include treatments of cabergoline administered orally for 10 days at a dose of 5 μg/kg combined with a single subcutaneous injection of 2.5 μg/kg cloprostenol at the start of the treatment; cabergoline administered orally for 10 days at a dose of 5 μg/kg combined with two subcutaneous doses of 1 μg/kg cloprostenol administered on the twenty-eighth and thirty-second day after the LH surge; bromocriptine administered orally at a dose of 30 μg/kg three times a day for 10 days plus a single subcutaneous dose of 2.5 μg/kg cloprostenol; bromocriptine at a dose of 30 μg/kg three times a day for 10 days plus two doses of 1 μg/kg cloprostenol. These combinations were administered to groups of five bitches starting at 28 days after the LH surge, and treatment was successful at inducing fetal resorption without overt abortion in all bitches except one that was administered the cabergoline and 1 μg/kg cloprostenol on the twenty-eighth and thirty-second day after the LH surge. Some bitches that resorbed litters had red cells, neutrophils, and cellular debris in the vaginal cytology smears for 4 to 21 days after treatment. All treated bitches did become pregnant on the subsequent estrous cycle, which occurred sooner than normally anticipated. The side effects of treatment included those commonly seen with prostaglandin when the high dose of cloprostenol was used, but the signs were not seen when the lower dose of cloprostenol was administered.[26] Using either a combination of increasing amounts of bromocriptine mesylate (15 to 30 μg/kg orally, every 12 hours) and dinoprost tromethamine (0.1 to 0.2 mg/kg subcutaneously, every 24 hours), or bromocriptine mesylate (15 to 30 μg/kg orally, every 12 hours) and cloprostenol sodium (1 μg/kg subcutaneously every 48 hours) resulted in 100% success in inducing abortion in 25 bitches.[27] Side effects included pseudopregnancy and a mucoid sanguineous vulvar discharge for 3 to 10 days.

In an attempt to shorten the treatment period required to induce abortion with $PGF_{2\alpha}$, combination therapy with injectable $PGF_{2\alpha}$ and intravaginal PGE1 (misoprostol) has been used.[28] Prostaglandin was administered at a dose of 0.1 mg/kg subcutaneously three times a day for 2 days and then at a dose of 0.2 mg/kg subcutaneously three times a day to effect. Misoprostol (Cytotec, Pharmacia, Peapack, New Jersey) was administered at a dose of 1 to 3 μg/kg, deposited into the cranial vaginal vault once daily using a cat pilling device. The mean time to complete abortion in nine bitches using this combination was 5 days, as compared with a mean of 7 days previously reported for complete abortion induced with $PGF_{2\alpha}$ as a sole agent.

250.5 OTHER DRUGS

Drugs that have been investigated but are not commonly used to induce abortion in practice situations include isoquinolones, progesterone receptor antagonists, progesterone synthesis inhibitors, and progesterone blockers. The antiprogesterone compound mifepristone (Mifeprix, Danco, New York, NY), more commonly known as RU 486 or RU 38486 for its use in preventing human pregnancies, works by preventing the progesterone binding to uterine progesterone receptors and therefore preventing the action of progesterone from occurring. Oral administration of mifepristone at a dose 2.5 mg/kg twice daily for 4.5 days starting at the thirty-second day of gestation resulted in 100% (5/5) of the bitches having a decline in progesterone 2 days after treatment started and pregnancy loss with no side effects around 3 days after treatment initiation.[29] Four pregnancies were terminated in bitches that were at 35 to 39 days gestation using oral mifepristone.[30] Doses as low as 8.3 mg/kg and up to 20 mg/kg were administered orally for one or two treatments and abortion occurred within 2 to 11 days.[30]

Mifepristone is available as a 200 mg tablet in the United States but is not labeled to terminate pregnancy in the bitch. Expense may be a factor.

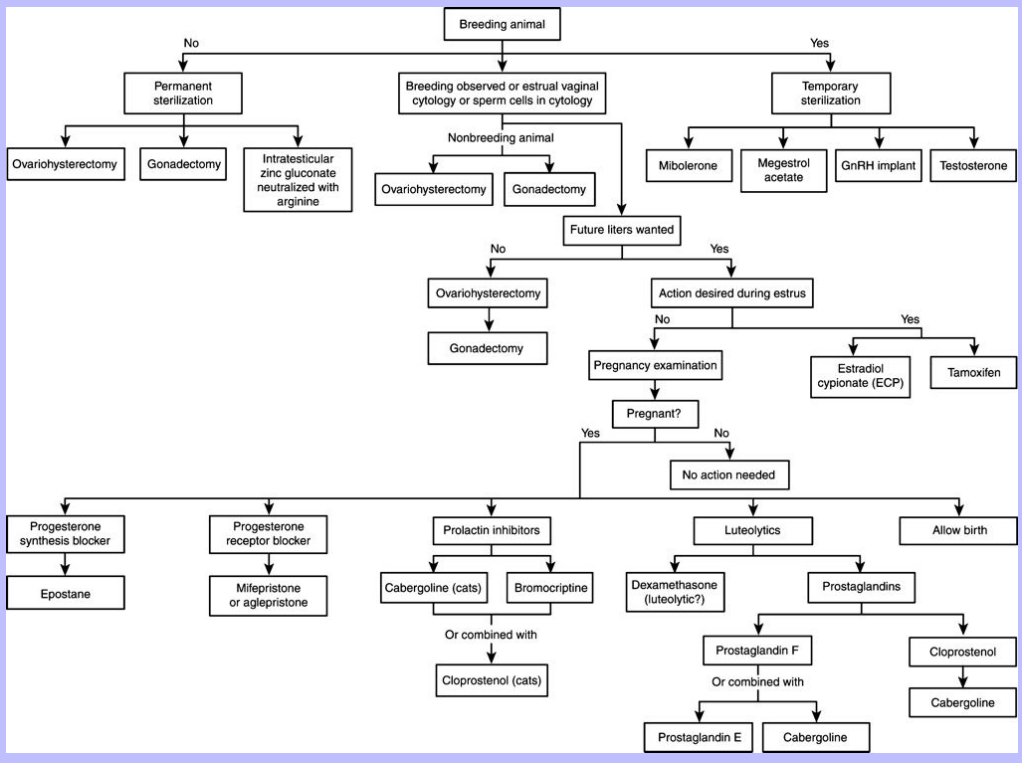
Aglepristone (Alizine) is another progesterone blocker that is available in France, Norway, and Sweden but not the United States to terminate pregnancy in the bitch. Two doses of 10 mg/kg given subcutaneously 24 hours apart from day zero to the twenty-fifth day or on the twenty-sixth day to the forty-fifth day after mating caused uncomplicated abortions within 7 days in 100% (35/35) and 95.7% (66/69) of bitches, respectively.[31] If the bitch was in midpregnancy, a brown mucoid vaginal discharge was seen 24 hours before fetal expulsion. Other side effects included slight depression, transitory anorexia, and mammary gland congestion. A clinical trial using 124 bitches had similar effects, and fetal resorption occurred within 7 days with no subsequent reproductive effects noted.[32] In a subsequent study using the same dose at the thirtieth day of gestation, all (5/5) bitches aborted with no apparent side effects other than a slight mucoid discharge 1 week after administration.[33] A single bitch was bred and became pregnant after treatment.

Epostane inhibits steroid synthesis by inhibition of 3β-hydroxysteroid dehydrogenase and Δ5–4 isomerase, thereby preventing progesterone synthesis.[34] Epostane was 100% (23/23) effective at preventing whelping (compared with a 100% whelping rate for controls) when administered orally for 7 days at doses of 50 or 300 mg (given to beagle bitches weighing about 10 kg) starting the first day of diestrus.[34] No side effects were seen, and subsequent fertility was not affected because 94.8% (127/134) of all the bitches treated conceived on the next estrous cycle.[34] Epostane is not available in the United States.

1673

1674

Figure 250-1 Algorithm for breeding.



250.6 DEXAMETHASONE

Two recent studies have been done using two different dose regimens of oral dexamethasone from 30 to 50 days of gestation.[35,36] The most effective dose regimen was the administration of oral dexamethasone using a 10-day dose schedule as follows: 0.2 mg/kg twice a day for 7 days, 0.16 mg/kg in the morning of the eighth day, 0.12 mg/kg in the evening of the eighth day, 0.08 mg/kg in the morning of the ninth day, 0.04 mg/kg in the evening of the ninth day, and 0.02 mg/kg the morning of the tenth day. A 10-day dose regimen was more effective than a shorter 7.5-day dose regimen in terminating pregnancies. At the author's institution a dose of 0.2 mg/kg twice a day for 10 days is used, with no tapering of the dose. The author and colleagues have observed no more than the anticipated side effects from not tapering the dose.

The initial fetal deaths with dexamethasone treatment were 5 to 9 days after initiation of the treatment; however, live fetuses were seen as long as 8 to 12 days after treatment started.[35] Pregnancies less than 40 days of gestation generally had no fetuses expelled, and the majority had no external signs of pregnancy loss.[36,35] A mild vaginal discharge was seen in only about 20% (26/75) of the bitches that resorbed fetuses. Abortion or resorption was generally complete 10 to 23 days after the treatment was initiated.[35] It is imperative that the pregnancy be re-examined with ultrasound and the drug continued until fetal death is noted. The treatment may fail if a treatment regimen is followed without checking for fetal loss. Although the exact mechanism of action is not known, dexamethasone may have a luteolytic effect. In the few bitches that had progesterone measured, the progesterone concentration fell to less than 1 ng/mL by the fourth day after treatment was initiated. If the initial treatment fails, a second treatment regimen may cause abortion, but most bitches treated a second time carried puppies to term.[35] Clinical failures have occurred using the recommended 10-day dose regimen. In the case of clinical failure, it may be advisable to treat with prostaglandin.

The main side effects of dexamethasone treatment include polydipsia and polyuria.[36,35] The polydipsia and polyuria usually began around 2 to 3 days after treatment started and were maximal 4 to 5 days later. The side effects generally subsided 3 to 4 days after the termination of treatment. Polydipsia and polyuria are not serious side effects but may be undesirable for dogs housed indoors in colder climates.

Successful pregnancies were obtained in 18 of 20 bitches bred during the first estrus after treatment and 2 of 2 on the second estrus. Therefore dexamethasone treatment appears to have no deleterious effects on future pregnancies and oral dexamethasone appears to be a safe, efficacious abortifacient in the bitch. Because dexamethasone is so readily available, inexpensive, has relatively minor side effects reported, does not require hospitalization, and is effective, it is the method recommended. Although not the ideal drug, it offers the most advantages of the ideal mismate drug when compared with all the other products available.

250.7 QUEEN

250.7.1 Permanent Sterilization

The same techniques applied to the canine can be applied to the feline, however much less information is available on the effects of OHE or ovariectomy on the queen. Toms are most commonly castrated; however, interest in sterilizing feral cats has led to some research on baited oral contraceptives. No intratesticular injections are approved for cats.

250.7.2 Termination of Pregnancy

The request for mismating or aborting queens is not common. Many of the same drugs can be used for mismate in cats as are used in dogs; however, the list is not nearly as inclusive. Pregnancy in the cat has similar aspects as the dog, in that the ovaries and corpora lutea are needed throughout pregnancy. Any drug altering luteal function will cause a queen to abort. The same strategy for determining pregnancy and the value of OHE can be used in the queen as in the bitch. The following drugs have been investigated for mismate in the queen.

250.7.3 Estrogen

Estrogen can be used shortly after copulation if an unwanted breeding was observed. Estradiol cypionate at a dose of 250 μg intramuscularly administered 6 days after coitus retarded embryo transport in the oviduct and also retarded ova development.[37] A single dose of 0.125 to 0.25 mg/cat of ECP given intramuscularly 40 hours after coitus has been suggested as an effective mismating regimen; however, no data is available on its efficacy.[38] Administration of ECP has the same potentially serious side effects in the queen as in the bitch (such as pyometra or aplastic anemia); however, the incidence is apparently less than the low incidence seen in the bitch.

250.7.4 Prostaglandin

Recent research investigating the period in gestation at which prostaglandin is most successful at inducing abortion in the queen confirmed that greater than or equal to 40 days appears to be a critical time for effectiveness.[39] Prostaglandin administration at doses associated with acceptable side effects before that time does not induce luteolysis. Despite the apparent resistance to abortion seen in other studies before the fortieth day of gestation, daily administration of 2 mg/cat $PGF_{2\alpha}$ subcutaneously for 5 days resulted in 100% (3/3) abortion when administered from the thirty-third day after mating.[40] However, queens exhibited nausea, vomiting, diarrhea, and prostration starting 10 minutes after treatment and continuing for an hour. All queens aborted fetuses within 6 days. This success before the fortieth day of gestation may be related to the timing of gestation from coitus. It is more difficult to measure the exact length of gestation in the queen compared with the dog, because estrus lasts about 8 days, regardless of the day of coitus. A subcutaneous dose of 0.2 mg/kg $PGF_{2\alpha}$ given twice the first day, followed by 0.5 mg/kg twice daily for up to 5 days was given to four queens at 30 days of gestation and four queens at 45 days of gestation.[39] One of four queens at 30 days aborted, whereas 75% (3/4) of queens at 45 days aborted. Queens that aborted had progesterone values less than 1.0 ng/mL, therefore verifying the eventual luteolytic effect of the prostaglandin.

250.7.5 Prolactin Inhibitors

Oral cabergoline at a dose of 5 to 15 μg/kg administered to feral cats 36 to 40 days of pregnancy for 4 to 9 days caused abortion in all (41/41) queens.[41] Combinations of prolactin inhibitors and prostaglandin have also been used to terminate pregnancy in the queen.[42] Cabergoline was administered orally at a daily dose of 5 μg/kg, and cloprostenol was administered subcutaneously every 2 days at a dose of 5 μg/kg starting at the thirtieth day after coitus. All (5/5) queens aborted after an average of 9 days of treatments. No side effects were seen, and queens that were bred subsequently became pregnant.

250.8 SUMMARY

Managing a mismate or pregnancy termination must be discussed with the client. Not using drugs and performing an OHE is usually the best alternative. If drugs are to be used, their use must be discussed with the client regarding safety, efficacy, convenience, compliance in treatment, side effects, and cost. As with most treatment regimens, familiarity with one treatment sometimes overrides using a superior method. It is therefore important to be aware of the most current literature available regarding protocols.

251 CHAPTER • 251 Cystic Endometrial Hyperplasia and Pyometra

Margaret V. Root Kustritz

251.1 INTRODUCTION

Pyometra is a chronic disease process with acute manifestation most commonly observed during the luteal phase of the estrous cycle, within 8 weeks of standing heat or ovulation induction.[1,2] Pyometra (from Greek, literally, "pus in the uterus") occurs when bacteria colonize a uterus with progressive hormone-mediated cystic hyperplasia of the endometrium. An inflammatory component is present, but the term *pyometra* is preferred to other published terms including pyometritis, catarrhal endometritis, and chronic cystic endometritis.[2–4] At no time should pyometra be confused with postpartum metritis.[2,5]

Incidence of pyometra in dogs and cats in the United States is poorly described, largely because the majority of bitches and queens are spayed relatively early in life in the United States. Many fewer bitches and queens undergo elective ovariohysterectomy (OHE) in European countries. It was reported in a Swedish study that 23% to 24% of bitches develop pyometra by 10 years of age.[6]

251.2 PATHOGENESIS

Pyometra has a two-step pathogenesis. The primary insult is development of cystic endometrial hyperplasia (CEH). The secondary insult is bacterial infection. A recent publication attempting to separate pyometra from CEH was unable to demonstrate independent development of the two entities in clinically ill bitches.[7]

CEH is a hormone-dependent change that develops after repeated estrous cycles in the bitch or queen. This histopathologic change can be induced experimentally with administration of either estrogen or progesterone, with progesterone having a greater effect.[8–10] Experimentally, the condition develops most quickly if progesterone is administered after priming with estrogen, as occurs during the spontaneous estrous cycle in bitches and in queens induced to ovulate.[10] Dogs that develop pyometra have not been demonstrated to have higher endogenous serum progesterone concentrations than normal dogs.[11] However, the normal down-regulation of estrogen receptors in the presence of rising serum progesterone concentrations may not occur in dogs with CEH-pyometra.[12,13] The progesterone-dominated uterus is more susceptible to proliferative and inflammatory changes, as has been demonstrated in studies in which uterine biopsies, scarification of the endometrium, or infusion of bacteria from bitches with pyometra into the uterus of healthy bitches were performed during the luteal phase.[14–17]

Another hormone that may be involved is insulin-like growth factor I (IGF-I). It has been demonstrated that the number of receptors for mitogenic IGF-I is higher in the uterus of bitches with pyometra than in normal bitches.[18] Serum concentration of prostaglandin metabolites also has been demonstrated to be elevated in bitches with pyometra; significance of this is unknown.[19]

Cats are considered to be induced (reflex) ovulators. However, a relatively high incidence of uterine disease in cats housed alone or with no exposure to an intact tom cat has promoted research that has documented apparent

spontaneous ovulation to occur in as many as 39% to 40% of queens.[20–22] A tentative diagnosis of pyometra should not be discounted in queens with no known history of coitus.

Administration of exogenous hormones, especially estrogens (diethylstilbestrol [DES], estradiol cypionate [ECP]) and progestins (megestrol acetate, medroxyprogesterone acetate), may hasten development of CEH and subsequent pyometra in bitches and queens.[18,23,24] In one study of eight dogs with CEH-pyometra at the uncommonly young age of less than 3 years, six of eight had received exogenous ECP or megestrol acetate in the previous 6 months.[24]

Secondary bacterial infection is the next step in the pathogenesis of pyometra in bitches and queens. CEH can occur independent of infection or may be associated with formation of sterile intrauterine fluid (hydrometra or mucometra).[25,26] The most common bacterial organism isolated from the infected uterus of bitches and queens is *Escherichia coli*.[4,15,20,27] The biotype of *E. coli* associated with pyometra in a given bitch or queen has been identified to be virtually identical in most cases to that animal's biotype of fecal *E. coli*.[28,29] Other organisms that may be isolated include *Staphylococcus* spp., *Streptococcus* spp., *Proteus mirabilis*, and *Pseudomonas aeruginosa*.[4]

The development of pyometra in bitches and queens transpires thus: (1) development of CEH over repeated cycles; (2) movement of normal vaginal bacterial flora into the uterus during proestrus and estrus[30]; (3) functional closure of the cervix, decreased myometrial contractility, and increased secretory activity of uterine glands during the progesterone-dominated luteal phase; (4) colonization and overgrowth of coliform bacteria or other organisms with secondary endotoxemia (in coliform infections) and renal disease. Studies[15,31] have shown bitches with pyometra to be predisposed to lymphopenia and decreased lymphocyte function, as well as to neutrophil damage with subsequent decrease in phagocytic capacity of PMNs.

Conditions that may develop subsequent to pyometra include septic shock and renal failure. Lipopolysaccharide endotoxins released from the cell wall of Gram negative organisms stimulate release of cytokines, such as tumor necrosis factor (TNF), interleukins (Ils), and platelet activating factor (PAF), which cause vasodilation and subsequent decreased intravascular volume and tissue perfusion.[32] Cardiac arrhythmias may occur in animals with septic shock.[33] Hypoglycemia and hepatocellular damage commonly occur secondary to septicemia.[33]

Renal dysfunction secondary to pyometra is due to decreased renal tubular concentrating ability as the result of endotoxemia and possibly to glomerular changes.[3] Mild tubulointerstitial nephritis and other renal tubular changes have been reported to occur in as many as 38% of bitches with pyometra.[34] Glomerular filtration rate (GFR) has been demonstrated to be decreased in up to 75% of bitches with pyometra and azotemia; glomerular lesions were not demonstrated by histopathology in that study.[35] Other studies have reported glomerulonephritis development secondary to deposition of antigen and antibody complexes in the glomeruli.[2] Renal disease secondary to pyometra usually reverses with successful treatment for pyometra.

251.3 SIGNALMENT AND HISTORY

CEH develops after repeated cycles, so CEH-pyometra is usually a disease of older bitches and queens. CEH with minimal to no inflammatory component has been demonstrated to occur at an average age of 7.2 years in bitches.[9] Reported mean age at time of development of pyometra in bitches is 7.8 years, with a reported range of

1 to 15 years and a reported majority in bitches over 6 years of age.[4,24,36,37] Mean age at time of diagnosis of pyometra in queens is 5.3 years, with a majority of cases occurring in queens aged 5 to 6 years or more.[21,24,28]

Reported risk factors include breed, parity, and body condition. Breeds described to be at increased risk in two studies are the golden retriever, rough collie, rottweiler, and Cavalier King Charles spaniel.[6,37] Mongrels are at decreased risk.[37] In several studies, nulliparous animals have been described to be at increased risk of developing CEH-pyometra.[21,37] However, in queens, no correlation was noted between likelihood of developing pyometra and age at first breeding, or occurrence of breeding or queening.[38] One survey in bitches reported that less than 50% of bitches with pyometra were nulliparous.[23] Anecdotal reports suggest that pyometra may be more likely to occur in middle-aged to old queens that are morbidly obese than in older queens with normal body condition.[39]

Bitches with a history of false pregnancy (pseudocyesis) are not at increased risk for development of pyometra. Serum progesterone concentrations do not differ between normal bitches, bitches with a history of false pregnancy, and bitches with pyometra.[11] In a survey of dogs with pyometra compared with age-matched controls, the dogs with pyometra were significantly less likely to have a history of false pregnancy.[36]

Pyometra is usually diagnosed during the luteal (progesterone-dominated) phase of the estrous cycle. Reported mean interval from the last known standing heat in dogs to onset of clinical signs of pyometra is 7.1 weeks, with a range of zero to 15 weeks.[1,4,9,24,40] Reported mean interval from the last known heat in queens to onset of clinical signs of pyometra is 3.8 weeks.[24]

251.4 CLINICAL SIGNS

Dogs and cats with uncomplicated CEH or presence of sterile intrauterine fluid (hydrometra or mucometra) may be asymptomatic.[25,26,38] Clinical signs in bitches and queens with pyometra vary depending on patency of the cervix. As might be expected, cervical patency (open cervix pyometra) is associated with presence of vulvar discharge, and cervical impatency (closed cervix pyometra) is more commonly associated with abdominal distension (Table 251-1). Vulvar discharge is usually purulent; it is creamy, red-brown to green in color, and foul smelling. Onset of clinical signs may be acute or gradual; in general, more severe clinical signs are associated with cervical impatency.[5,9]

251.5 DIAGNOSIS

Definitive diagnosis of pyometra requires demonstration of presence of purulent fluid within the uterus. A tentative diagnosis is made by demonstration of uterine enlargement in a nonpregnant bitch or queen and usually is associated with clinical signs and physical examination findings of systemic disease and hematologic changes. A complete work-up for dogs and cats with possible pyometra includes a physical examination; radiography or ultrasonography of the abdomen; a complete blood count (CBC), serum chemistry profile and urinalysis; urine culture; and possibly measurement of progesterone in serum. Ancillary tests are performed as needed (e.g., culture of free abdominal fluid in pets with possible peritonitis and a coagulation profile in animals with overtly hemorrhagic discharge).

Physical examination findings often are unremarkable in dogs and cats with uncomplicated CEH. Severity of physical examination findings generally is greater in animals with closed cervix pyometra than in those with

open cervix pyometra. Uterine enlargement may or may not be palpable (Table 251-2). Caution must be used when palpating a potentially friable distended uterus in any animal with possible pyometra.

Table • 251-1 Reported Mean Prevalence of Clinical Signs in Bitches and Queens with Pyometra

	BITCHES (%)	QUEENS (%)
Purulent vulvar discharge	87	59
Lethargy	72	32
Anorexia	73	40
Abdominal distension	—	17
Polyuria/polydipsia (PU/PD)	28	9
Vomiting	36	16
Diarrhea	27	—

Table • 251-2 Reported Prevalence of Physical Examination Findings in Bitches and Queens with Pyometra

	BITCHES (%)	QUEENS (%)
Palpable uterine enlargement	31–40	68
Purulent vulvar discharge	75	39
Dehydration	15–28	33
Fever (>102.5° F)	41–43	20
Hypothermia (<100.0° F)	3	—

From Hardy RM, Osborne CA: Canine pyometra: pathophysiology, diagnosis and treatment of uterine and extra-uterine lesions. J Am Anim Hosp Assoc 10:245–268, 1974; Wheaton LG et al: Results and complications of surgical treatment of pyometra:a review of 80 cases. J Am Anim Hosp Assoc 25:563–568, 1989; Kenney KJ et al: Pyometra in cats: 183 cases (1979–1984). J Am Vet Med Assoc 191:1130–1132, 1987.

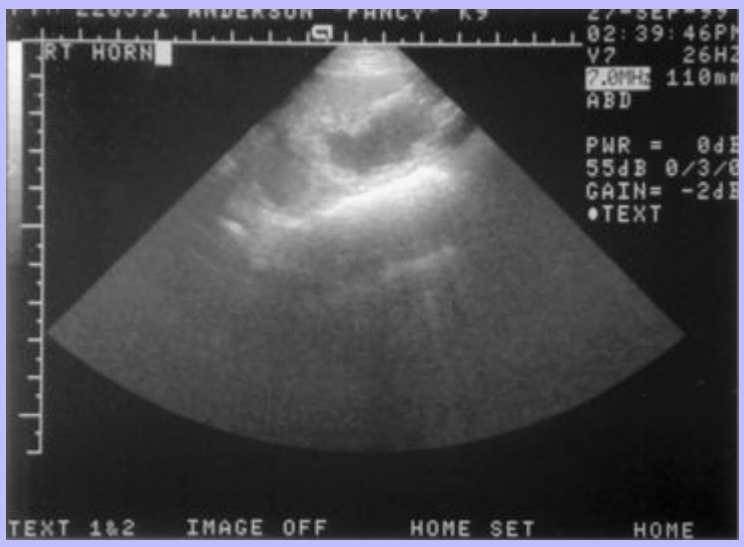
Cervical patency is inferred from presence or absence of vulvar discharge. A narrow diameter endoscope may be passed the length of the vagina to attempt to see the cervix but usually it is only the appearance of fluid moving into the cranial vagina that allows one to state that the cervix is functionally open.[30]

Nonreproductive abnormalities that may be detected by physical examination in dogs and cats with pyometra include dehydration, which occurs secondary to renal disease, fever, and anorexia; fever due to infection; hypothermia due to septicemia or shock; and abdominal pain, which may be evident in animals with uterine distension or peritonitis due to leakage of purulent material from the uterus (see Table 251-2).[4,24,27,41]

Uterine enlargement that cannot be assessed by physical examination may be detected by abdominal radiography or ultrasonography. Pyometra occurs during diestrus; radiographic demonstration of uterine enlargement prior to 42 to 45 days postestrus may not allow differentiation of pyometra from pregnancy. Abdominal ultrasound is a more definitive diagnostic technique. Ultrasonographically, CEH appears as a fluffy, irregular, mottled thickening of the endometrium on uterine horns viewed in cross-section (Figure 251-1). CEH may not be visible in animals with distension of the uterine horns caused by large volumes of intrauterine fluid. Fluid-filled uterine horns are observed without difficulty in dogs and cats with pyometra and can readily be differen-tiated from pregnancy by 24 to 25 days postbreeding (Figure 251-2).[2,42]

Hematologic changes reported in dogs and cats with pyometra include changes in white blood cell (WBC) number and anemia. Leukocytosis, often to greater than 30,000 cells/μL, is reported to occur in 62% to 68% of dogs and 66% of cats with pyometra.[24,27,31] A regenerative left shift and monocytosis may accompany the leukocytosis. These changes are characteristic of a suppurative and exudative inflammatory process such as pyometra.[43] Lymphopenia is reported to occur in 8% to 35% of dogs and 5% of cats with pyometra.[24,27,31] Anemia of chronic infection is reported to occur in 25% of dogs and 4% of cats with pyometra.[24,27,43] Thrombocytopenia is rarely reported in dogs with pyometra and may be a component of disseminated intravascular coagulation (DIC).[43] Erythrocyte sedimentation rate is reported to be elevated in bitches with pyometra compared with normal diestrual bitches; usefulness of this change as a diagnostic test is equivocal.[44]

Figure 251-1 Ultrasound image of cystic endometrial hyperplasia (CEH) in a bitch. Reader should note the fluffy, mottled lining of the uterine wall on cross section.



No changes are seen in the serum chemistry profile that are pathognomonic of pyometra in dogs and cats.[44] Azotemia due to dehydration and possible renal dysfunction is reported to occur in 18% to 26% of dogs and 12% of cats with pyometra.[4,27,35] Other changes that are present commonly include hyperproteinemia and increased alkaline phosphatase (ALP) and alanine transaminase (ALT).[2,27]

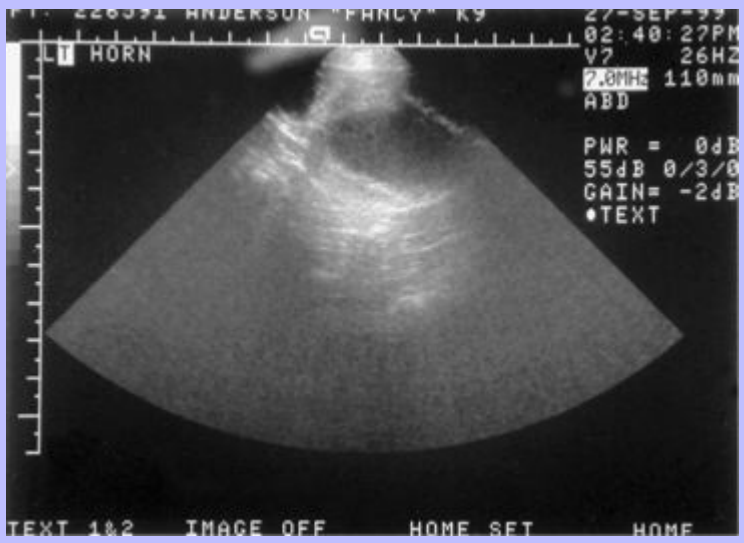
Urinalysis findings are suggestive of secondary renal disease. Proteinuria may or may not be present, regardless of presence of azotemia.[4,35] Urine specific gravity (USG) varies with hydration status and presence of polyuria due to renal disease subsequent to endotoxemia; in one study of 27 dogs with pyometra, 89% had USG less than 1.035.[35] In that same study, 22% of the dogs had concurrent urinary tract infection.[35]

Increases in serum progesterone concentration promote quiescence of the myometrium and may decrease efficacy of medical therapy. Although dogs and cats generally have clinical signs of pyometra while in diestrus,

16% to 38% of bitches and 20% of queens have been reported to have serum progesterone concentrations of less than 1 ng/mL at the time of diagnosis.[15,20,40] This may be due to release of endogenous prostaglandin from the diseased endometrium with subsequent luteolysis. Knowledge of serum progesterone concentration may alter course of treatment.

1678
1679

Figure 251-2 Ultrasound image of pyometra in a bitch. Reader should note the uterine horns distended with fluid.



251.6 TREATMENT

OHE is the best treatment of pyometra in dogs and cats. The underlying pathologic change, CEH, cannot be reversed with medical therapy. All animals with CEH are predisposed to pyometra after each subsequent estrus. Recurrence of secondary infection has been demonstrated to occur commonly with the biotype of organism that was causative of pyometra historically in a given animal, suggesting that medical therapy does not clear infection in all cases but rather decreases infection to a subclinical level.[45]

Complete OHE is always recommended. Caution must be used when handling the friable, distended uterus. Ovariectomy alone is reported to cause resolution of clinical signs of pyometra in dogs in 5 to 15 days.[9] This response probably is due to an iatrogenic decrease in serum progesterone concentration and is not a quick enough response to provide relief for critically ill animals.

Other surgical therapies reported involve placement of in-dwelling catheters transcervically to allow flushing of the uterus with antiseptic compounds or mucolytic agents.[4,46] Success with such techniques is not well described, and this mode of therapy is not recommended.

Medical therapy for pyometra is most appropriate for dogs and cats with a patent cervix. Medical therapy for animals with closed cervix pyometra has been reported.[23,43,47] Administration of ecbolic agents cause uterine contractions that propel purulent fluid against the internal cervical os and cause cervical dilation. However, in one survey of 30 dogs with pyometra, 13% had positive bacterial cultures of abdominal swabs despite lack of

uterine rupture, suggesting leakage of purulent material through the friable uterine wall or via the uterine tubes.[15] All reported cases of salpingitis (uterine tube inflammation) in dogs were in bitches with pyometra.[2] Finally, with no clear knowledge of viability of uterine tissue, it is impossible to know whether causing uterine contractions may not cause uterine rupture. For these reasons, medical therapy for animals with closed cervix pyometra is not recommended.

All dogs and cats with pyometra, whether treated by OHE or medically, must be treated with antibiotics. An appropriate antibiotic choice is made based on culture and sensitivity testing of vulvar discharge or intrauterine content at the time of OHE. Good empiric choices for use while culture results are pending are ampicillin (22 mg/kg per os three times daily) and amoxicillin-clavulanate (14 mg/kg per os two times daily). Antibiotics should be administered for 2 to 4 weeks after OHE and until vulvar discharge is no longer evident in those animals treated medically. The bacterial infection of pyometra may be difficult to eradicate because of inability of antibiotics to diffuse into the pool of intrauterine fluid and possibly because of spontaneous formation of a glycocalyx biofilm that may bind antibiotics, again preventing ability of the antibacterial agent to reach embedded bacterial cells.[46]

Medical therapy for dogs and cats with pyometra can be considered if (1) the cervix is open, evidenced by presence of vulvar discharge; (2) the animal is still of breeding age, generally 6 years of age or less for dogs and 8 years of age or less for cats; (3) the animal is a valuable component of a breeding program; and (4) no evidence exists of renal disease or other sequelae to the pyometra. The effect of medical therapy may not be evident for up to 48 hours after initiation of treatment.[5] The author feels it is unethical to prolong the animal's suffering unnecessarily if secondary disease is present.

Antibiotic therapy alone will not affect a cure in dogs and cats with pyometra. An ecbolic agent, which causes uterine contractions and promotes expulsion of the purulent fluid, must be administered concurrently. The best-described ecbolic agent for use in treatment of pyometra in small animals is prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$). $PGF_{2\alpha}$ causes uterine contractions when administered once or twice daily and causes luteolysis when given twice daily. Because most animals with pyometra are in diestrus and may have increased serum progesterone concentrations, it may be beneficial to measure serum progesterone concentrations to determine if administration of luteolytic doses of $PGF_{2\alpha}$ is required. Prostaglandins cannot effect luteolysis in the first 5 days of diestrus in dogs at any dose and are not as effective a luteolytic agent in cats as in dogs. Analogues of $PGF_{2\alpha}$ such as cloprostenol, also are ecbolic and luteolytic in dogs and cats, but all doses described here refer to the native compound and should not be used with analogues.

$PGF_{2\alpha}$ is administered subcutaneously, at doses of 0.1 to 0.25 mg/kg.[23,47,48] Some authors recommend a gradual increase in dose over the first 48 to 72 hours of treatment to minimize side effects.[48] The lower end of the dose range generally is recommended for treatment of queens. Infusion of $PGF_{2\alpha}$ into the vaginal lumen also has been described in dogs.[49] $PGF_{2\alpha}$ is administered until the uterus nears normal size, as determined by abdominal palpation, radiography, or ultrasonography. In most cases, less than 7 days of treatment are required.[47]

Side effects of $PGF_{2\alpha}$ are referable to its causing contractions of the gastrointestinal (GI) tract and include hypersalivation, vomiting, and diarrhea. Queens may exhibit excessive grooming and restlessness. Side effects generally occur within 5 to 15 minutes of drug administration, subside within 30 to 60 minutes, and usually lessen in severity with each subsequent injection. The clinician can minimize side effects by using lower doses of $PGF_{2\alpha}$, by diluting the volume of $PGF_{2\alpha}$to be given with normal saline before administration, and by walking

dogs after it is given. Concurrent administration of atropine (500 mg/kg intramuscularly) also may be beneficial.[2] $PGF_{2\alpha}$ is not approved for treatment of pyometra in dogs and cats in the United States.

Progesterone receptor blockers, for example mifepristone and aglepristone, are reported to be efficacious for treatment of pyometra in dogs and cats, with minimal side effects.[50–52] These drugs are not available for veterinary use in the United States. Other compounds described for treatment of pyometra, none of which are recommended, include estrogen, androgens, oxytocin, and ergot alkaloid derivatives.[9,48]

Ancillary supportive therapy to be used includes intravenous fluid therapy and maintenance of normal body temperature. Other ancillary treatments reported for treatment of pyometra in dogs and cats include use of hypertonic saline with 60% dextran to combat septic shock and promote renal blood flow, use of hemoglobin glutamer-200 to enhance tissue delivery of oxygen in animals with poor oxygenation secondary to shock, and treatment with equine-derived antibodies against endotoxin to combat renal disease due to endotoxemia.[32,53,54]

At the subsequent estrus, a sample should be collected from as far forward in the vagina as possible early in proestrus (bitches) or estrus (queens), and appropriate antibiotic therapy should be administered for at least the duration of proestrus and estrus while the cervix is open and the uterus is vulnerable to infection with bacteria ascending from the vagina. Antibiotic therapy is recommended even if the bitch or queen will not be bred during that estrus. Because fertility is compromised and because the bitch or queen still has CEH and a predisposition to pyometra, she should be bred and all desired offspring obtained as quickly as is feasible. The dog or cat should then be spayed as soon as her breeding life is over or if pyometra recurs.

1679

1680

251.7 PROGNOSIS

Spontaneous resolution of mild inflammatory changes overlying CEH has been reported to occur subsequent to plasma cell infiltration.[10,55] Animals with pyometra do not recover spontaneously.

Overall reported success rate for treatment of pyometra in dogs ranges from 46% to 100%; reported success rate for treatment of pyometra in one study was 92% in cats.[2] In general, those animals that do not recover have concurrent disease or complications due to sepsis or toxemia.[24]

After medical therapy, reported prevalence of recurrence of pyometra in bitches is 10% to 77% within 27 months of therapy.[2,45] Other reported long-term complications include persistent anestrus, failure to conceive, and spontaneous abortion.[23] In two studies evaluating fertility of bitches after medical treatment for pyometra, reported percentages of dogs bred that went on to whelp were 64% and 87%.[23,48] In the former study, prognosis for future fertility was best in those animals requiring less than 6 days of treatment with $PGF_{2\alpha}$.[23] Prognosis for future fertility generally is better in queens, with a reported queening rate of 90% in those queens bred after medical therapy for pyometra.[2]

251.8 UTERINE STUMP PYOMETRA

Pyometra of the uterine stump occurs rarely in dogs and cats. It is assumed to be associated with remnant ovarian tissue or administration of exogenous estrogen or progestins in most cases, because any remnants of endometrial tissue should be quiescent in the absence of hormonal stimulation. Clinical signs are as described for pyometra in intact animals. Diagnosis is best made by abdominal ultrasound; pyometra of the uterine stump appears as a

cystic mass near the bladder. Diagnosis of ovarian remnants is described in Chapter 247. Treatment includes systemic antibiotic therapy and surgical removal of the uterine stump and ovarian remnants, if any.

251.9 CONCLUSION

CEH is a hormone-mediated gradual change of the uterine lining. Presence of CEH predisposes the uterus to infection; infection overlying CEH with subsequent formation of intrauterine purulent fluid is pyometra. Nulliparous animals may be predisposed; those animals with a history of false pregnancy are not predisposed to pyometra. Diagnosis requires demonstration of uterine enlargement and presence of purulent intrauterine fluid. Neutrophilia with a regenerative left shift and monocytosis often are present. Secondary renal disease may occur subsequent to endotoxemia in dogs and cats with coliform infection. OHE is the treatment of choice in most cases. Medical therapy with $PGF_{2\alpha}$ may be attempted in young, valuable bitches and queens with a patent cervix and no evidence of secondary renal disease.

252 CHAPTER • 252 Canine Female Infertility

Gary C.W. England

252.1 INTRODUCTION

Over recent years there has been increased awareness of canine female infertility, particularly in dogs bred for working and showing purposes. The true extent of infertility is unknown, although reproductive failure is common. It is with increasing frequency that breeders and managers of breeding colonies approach their veterinarian for help with reproductive problems. In some circumstances reduced fertility may not be fully appreciated because breeding is relatively infrequent when compared with other domestic species. In addition, wide breed variations exist (particularly in litter size) that make it difficult to compare animals of different breeds. Certain breeds appear to have an increased incidence of infertility.

The normal expectation of fertility in the bitch is a whelping rate of 70% to 80% after mating to a male with normal semen quality. Variations from this exist, depending in particular upon the age of the bitch. Average peak reproductive efficiency occurs at approximately 3 years of age, and a significant decline occurs in the number of pups born to bitches aged 7 years and older.[1]

The investigation of infertility is complicated by the fact that fertility problems may be difficult to recognize. Failure to conceive does not result in an immediate return to estrus. Furthermore, pseudopregnancy is a normal physiologic event and, in some bitches that do not whelp, the owner may have confused the signs of pseudopregnancy with pregnancy. However, the early diagnosis of pregnancy is now possible using ultrasonography, the detection of acute-phase proteins in serum, and the measurement of serum relaxin concentrations. Early pregnancy diagnosis helps allow prompt investigation into why an individual bitch fails to produce live offspring.

As with other species, the causes of infertility may be classified as structural (including congenital, acquired, and neoplastic diseases), functional (including endocrinologic abnormalities), infectious, or managemental. However, what is most helpful to the clinician is the way in which these cases are presented, namely (1) failure to cycle, (2) abnormal estrous cycles, (3) normal estrous cycles with failure of copulation, (4) normal estrous cycles with copulation (distant from ovulation) and conception failure, (5) normal estrous cycles with copulation (close to ovulation) but conception failure, or (6) normal estrous cycles and conception with subsequent pregnancy failure.[2]

252.2 INVESTIGATION OF INFERTILITY

Many cases of “infertility” are caused by a lack of owner understanding of normal canine reproductive physiology. For example, considerable normal variations exist in the onset of puberty between animals and in the timing of ovulation from the onset of proestrus.

The previous breeding history, including parity and litter size, together with information regarding the stud dog, are probably the most important factors (one of the common causes of infertility is related to the male). Additional information concerning the onset of puberty, present cyclicity, general medical history, and the administration of pharmaceutical compounds (steroids in particular) may also be useful. After a full clinical examination to rule out systemic disease, specific examination of the reproductive tract should be performed.

This should include inspection of the external genitalia, palpation of the mammary glands, digital examination of the vestibule and caudal vagina, and transabdominal uterine palpation.

Several other techniques are useful for the investigation of reproductive disease, including exfoliative vaginal cytology, vaginal endoscopy, transcervical collection of uterine cells to evaluate uterine disease, and ultrasound imaging of the ovaries and uterus. Laparoscopy and laparotomy may also be valuable for inspection of the uterus, uterine tubes, and ovaries but are infrequently used due to their invasive nature and the requirement for general anesthesia. Measurement of circulating hormone concentration has a number of indications. It can be used to confirm the presence of gonadal tissue, to detect hormone secreting neoplasms and cystic structures, and for the prediction and confirmation of ovulation.

252.3 CLINICAL PRESENTATIONS OF INFERTILITY

252.3.1 Failure to Cycle

Failure to cycle may be either primary (no estrus activity before 24 months [i.e., delayed puberty]) or secondary (no estrus activity within 12 months of a previous cycle [i.e., prolonged anoestrus]). In most cases a specific disease process may be responsible for this problem, and careful investigation for an underlying cause is important for appropriate treatment and prognosis. Estrus induction may be attempted with either primary or secondary failure when a specific cause has been identified.

252.3.1.1 Delayed Puberty

The age at puberty ranges between 6 and 24 months. Most bitches cycle within 1 to 6 months of attaining adult height and weight, and the age of puberty can be influenced by the breed, body weight, and environmental conditions. In general, bitches that do not reach puberty by 2 years of age are considered to have delayed puberty. It is common for there to be few signs associated with the first estrus and therefore some bitches which are thought to have delayed puberty may have simply had an unobserved estrus. Increased serum progesterone concentrations (> 2.0 ng/mL [6.5 nmol/L]) demonstrates that ovulation has occurred within the last 60 days (i.e., the estrus has been missed).

Investigation of delayed puberty involves collection of information on housing and diet (because poor environmental conditions and nutrition may be associated with failure to cycle) and a thorough clinical examination to rule out chronic debilitating disease.

An underlying chromosomal abnormality may also cause delayed puberty. Many of these bitches are phenotypically abnormal (having a small cranially positioned vulva and developing clitoral enlargement at puberty). A smaller propor-tion of bitches are phenotypically normal but have an abnormal complement of sex chromosomes that results in ovarian hypoplasia or ovarian dysgenesis. Establishing a karyotype usually demonstrates chromosomal abnormalities such as 77XO, 79XXX, 79XXY, and 78XX/78XY.[3] In normal bitches with no underlying disease, estrus induction can be attempted as described later.

252.3.1.2 Prolonged Anestrus

The average interestrus interval is 31 weeks; although some variation occurs around this mean value, this has no apparent effect on fertility. Certain breeds, for example the Basenji, cycle only once per year. The reason for these variations is unclear. Prolonged anestrus represents an interestrus interval greater than

anticipated for that particular animal (usually more than 12 months from the previous cycle). Failure of normal reproductive cyclicity has several causes. A common problem is the failure of observation of the signs of estrus, particularly in kenneled bitches. This may occur in fastidious bitches, which quickly remove any vulval discharge, or when the discharge is scant. Serum progesterone concentrations greater than 2.0 ng/mL (6.5 nmol/L) indicate a missed estrus and ovulation within the previous 2 months.

Initial investigations should include a thorough history and examination for chronic systemic disease and evaluation of the general body condition. Important factors in the history are any indications of chronic disease and any previous or concurrent treatments or medication. Drug-induced anestrus should be considered when the interestral interval is prolonged; pharmaceutical preparations that have the ability to prevent estrus include glucocorticoids, anabolic steroids, androgens, and progestogens. Investigation of thyroid function may also be useful because some evidence indicates a relationship between thyroid hormone insufficiency and abnormalities of the estrous cycle. Hypothyroidism has been associated with prolonged anestrus and infertility. The mechanism of this abnormality has not been fully established; however, prolactin is released after the injection of thyrotropin-releasing hormone (TRH). Therefore factors that affect endogenous TRH release probably affect prolactin and thyroid function. Low concentrations of serum thyroid hormones and failure to respond to a stimulation test may be used to confirm the condition, although clinically these animals usually have typical clinical signs associated with hypothyroidism. After replacement therapy most bitches return to estrus within 6 months. Interestingly however, hypothyroidism in greyhounds was not shown to be related to poor reproductive function[4] and a consistent relationship between thyroid disease and reproductive function has yet to be established. When no underlying disease is present, estrus induction may be attempted.

Progesterone-producing ovarian cysts have been described in the bitch, producing prolonged interestrus intervals and cystic endometrial hyperplasia. Ovarian cysts may be identified ultrasonographically and the diagnosis confirmed by serial measurement of serum progesterone concentrations. Medical treatment has not been successful, and usually the cystic ovary needs to be surgically removed. These cysts should not be confused with cysts originating from the ovarian bursa that are of no significance.

1681

1682

In some cases, ovarian neoplasms that produce either progesterone or androgens result in a failure to return to cyclical activity. Such tumors are rare and are usually associated with chronic wasting and an abdominal mass effect with ascites. Treatment is surgical removal.

Some bitches have normal cyclical activity, including follicular growth and ovulation, without obvious external signs of proestrus or estrus. This is often called *silent estrus* (silent heat) and is common in certain breeds, greyhounds for example. The condition may be the reason the owner overlooks the signs of estrus. Ovulation may be confirmed by measurement of serum progesterone concentration as described previously. Alternatively, the weekly examination of exfoliative vaginal cytology will allow anticipation and monitoring of estrus.

Premature ovarian failure has been suggested as a rare but permanent cause of anestrus in previously normal bitches.[5] For an accurate diagnosis of these cases, investigation of the karyotype and measurement of serum concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and thyroid hormone should be undertaken.[3] In valuable breeding animals, estrus induction regimens may be contemplated; however, no information is available concerning the efficacy of these treatments in animals with premature ovarian failure.

252.3.1.3 Induction of Estrus

Estrus-induction may be attempted when no underlying abnormality has been detected in bitches older than 2.5 years with delayed puberty or in bitches with prolonged anestrus. A variety of agents may be used for this purpose, including prolactin inhibitors (cabergoline or bromocriptine), equine chorionic gonadotropin (eCG) with human chorionic gonadotropin (hCG), gonadotropin-releasing hormone (GnRH), and estrogens. Unlike other domestic species, it is not possible to induce estrus by shortening the luteal phase using prostaglandins because the luteal phase is followed by a variable, but prolonged, period of anestrus.

The most useful method of estrus induction is the administration of prolactin inhibitors (although these may have a variable effect in bitches with delayed puberty). Prolactin plays a role in the regulation of interestrous intervals, possibly by affecting gonadotropin secretion, ovarian responsiveness to gonadotropins, or both. When prolactin inhibitors are administered daily (cabergoline at 5.0 μg/kg/day) during prolonged anestrus, a rapid return to estrus occurs (usually within 30 days). If treatment is stopped once proestrus has begun, a high pregnancy rate usually occurs that is similar to that seen in natural cycles.

For bitches with delayed puberty it may be necessary to attempt estrus induction using gonadotropins, if the administration of prolactin inhibitors fail. Many protocols have used exogenous gonadotropins for the induction of estrus, and commonly low doses of eCG (20 IU/kg for 5 days) with a single administration of hCG (500 IU/bitch on the fifth day) are recommended.

Although several reports document the value of estrogens and GnRH (either in pulses or the use of a superagonist), such regimes are not commonplace in clinical practice because whelping rates are relatively low.

252.3.2 Abnormal Estrous Cycles

252.3.2.1 Split Estrus

A short interval (2 to 12 weeks later) between clinical signs of estrus is often described as a *split estrus*. This occurs most frequently at the pubertal estrus but can occur at any age. An initial phase of follicular growth and estrogen secretion occur, but the follicles regress and signs of estrus disappear. Subsequently a second follicular phase appears. In some cases this may be repeated several times until finally the bitch ovulates normally. This syndrome is confusing because it may be thought that the bitch has failed to ovulate or that fertilization with subsequent resorption or abortion has occurred. The recognition of split estrus syndrome is important to ensure that mating is achieved at the correct time. In some cases, induction of ovulation may be attempted using hCG, although it can be difficult to be certain at which point to administer this preparation. This is most successful when administered at the peak of vaginal epithelial cell cornification.

252.3.2.2 Ovulation Failure

The frequency of ovulation failure is approximately 1% of estrus cycles,[6] and clinicians commonly make the diagnosis by serial monitoring of serum progesterone concentrations. This condition is likely to have a similar cause to those bitches with split estrus (possibly caused by low concentration of LH or LH

receptor). Attempts to induce ovulation during estrus using 500 IU/kg hCG between 1 day before to 1 day after the first mating may be successful.

252.3.2.3 Prolonged Proestrus or Estrus

The time at which bitches ovulate after the onset of vulval bleeding is very variable. Usually this is between the sixth and twentieth day after proestrus began. For the average bitch, the surge in serum LH occurs on the tenth day; ovulation follows 2 days later. However, many normal bitches do not ovulate at this time, and most bitches with alleged prolonged proestrus are actually at the extremes of normality; they simply ovulate later in the cycle than anticipated. In some, normal ovulation occurs 30 days after the onset of proestrus.

These animals do not require treatment, but careful assessment of the optimum mating time, usually by evaluation of vaginal cytology or measurement of serum progesterone (see later). It is unlikely that the administration of hCG would produce normal ovulation earlier in the cycle; however, little data is available on such use of this agent.

Estrogen-secreting follicular cysts may produce persistent estrus. These bitches may be brought to a veterinarian because of the inconvenience; however, the persistent elevation of serum estrogen can also lead to bone marrow suppression with anemia and thrombocytopenia.

Ultrasonographically large (8 to 12 mm diameter) fluid-filled follicles may be identified. These must be carefully differentiated from normal follicles and early corpora lutea, both of which have central fluid-filled cavities. Some follicular cysts respond to alternate-day administration of hCG on three occasions. Failing this, cysts may respond to progestogen administration using drugs such as megestrol acetate. With the latter an increased risk of pyometra is seen, because the progestogen is administered after a prolonged period of estrogen priming. Ovariectomy may be required if no response to exogenous hormone therapy is seen. Cyst-like structures are frequently identified around the ovaries at routine surgery. These are often parabursal in origin and have no significance on cyclicity or fertility.

252.3.2.4 Ovarian Neoplasia

Ovarian neoplasms are not common in the bitch, accounting for approximately 1.0% of all neoplasms.[7] The mean age of occurrence is 8 years, although some bitches may develop neoplasia as early as 7 months of age. Tumors that release estrogen may produce signs of persistent estrus and bone marrow suppression, although clinical signs are also often related to a mass effect or ascites. Neoplasia may be most effectively diagnosed at ultrasound examination. The tumors may be germ cell, epithelial, or sex-cord stromal in origin. They do not commonly metastasize. Ovariohysterectomy is the treatment of choice; care should be taken not to rupture neoplasms during surgery because metastatic spread is often by transcoelomic seeding. *1682*

1683

252.3.3 Normal Estrous Cycle with Failure of Copulation

252.3.3.1 Behavioral Problems

Some bitches are frightened and traumatized by attempted breeding and may refuse subsequent mating. Other bitches may be “humanized” or are too familiar with the male and do not exhibit normal estrus behavior. Observation of the bitch at attempted mating should allow identification of typical behavior

patterns that may include marked submission or aggression. Careful management of the virgin bitch is important to ensure that behavioral abnormalities do not become established.

252.3.3.2 Vestibulovaginal and Vestibulovulval Abnormalities

Strictures of the caudal reproductive tract are common. Circular strictures or transverse bands are usually found at the junction of the vestibule and the vagina, although vestibulovulval strictures can also be identified. Vestibulovaginal abnormalities are often first noted during attempted mating when they cause pain or a failure to achieve intromission. Small constrictions and fibrous bands may be manually broken down under general anesthesia when the bitch is in proestrus or estrus. Mating may be allowed later during the same estrus. Surgical exploration via an episiotomy may be required for larger transverse bands.

252.3.3.3 Vaginal Hyperplasia

Vaginal hyperplasia is an accentuated response of the caudal vaginal floor to normal circulating estrogen concentrations. Usually the vaginal mucosa cranial to the external urethral orifice is involved and becomes edematous and thickened. This mass of tissue may result in pain at coitus in some bitches, and in others it may rapidly increase in size and protrude from the vulva preventing coitus. The latter condition is sometimes referred to as a *vaginal prolapse* (correctly, it is a prolapse of hyperplastic vagina). Occasionally the circumference of the vagina and not just the floor may be involved.

In most bitches the mass decreases in size at the end of estrus, therefore conservative management with local cleansing and lubrication are sufficient. Ovariohysterectomy during the subsequent anestrus will prevent recurrence. In bitches that are required for breeding, artificial insemination may be necessary or submucosal surgical resection of the tissue performed during early estrus before mating. A minority of surgically treated cases recur; however, the use of surgery has been questioned because a familial tendency has been reported in certain breeds.[8] Although rare, true prolapse of the nonhyperplastic vagina has been reported during estrus when it also may prevent mating.

252.3.3.4 Congenital Anomalies of the External Genitalia

Hypoplasia of the vulva has been described and may be associated with pain at coitus and often a perivulval dermatitis. Considerable breed variation is seen in the normal vulval anatomy; for example, the greyhound has small external genitalia.

Congenital abnormalities including vulvar atresia and vulvar agenesis are rare, and may cause chronic vaginitis.

252.3.3.5 Vaginal Hypoplasia and Aplasia

Segmental aplasia of the Müllerian duct system may be *partial*, producing vaginal hypoplasia, or *complete*, resulting in vaginal aplasia. The condition is rare and may cause the retention of uterine fluid with signs similar to pyometra. Diagnosis may be made by palpation or positive-contrast radiographic examination of the vagina.

252.3.4 Normal Estrous Cycle with Copulation (Distant from Ovulation) and Conception Failure

The most common reason for failure of conception is inappropriate timing of mating. This is often because mating is planned a set number of days after the onset of proestrus (often the twelfth to the sixteenth day). Although the majority of bitches ovulate between 10 and 14 days after the onset of proestrus, some ovulate as early as the fifth day or as late as the thirtieth day. Therefore should a bitch be mated on the twelfth to the sixteenth day this can be inappropriate and result in failure of conception. A further complication is that bitches are not necessarily consistent in the day on which they ovulate between subsequent estrus cycles. Detecting the time of ovulation is difficult because the behavioral signs of estrus do not always correlate with the changes in peripheral hormones, and often the dog and bitch are not allowed to display normal courtship behavior.

252.3.4.1 Fertilization Period and Fertile Period

Spontaneous ovulation occurs approximately 48 hours after the surge in serum LH. Eggs are released as primary oocytes that must reach the metaphase of the second meiotic division before fertilization can occur. This maturation takes 48 to 60 hours. Oocytes remain fertilizable for a further 2 to 3 days, therefore the time span over which fertilization may occur, termed the *fertilization period*, is between 4 and 7 days after the LH surge (i.e., between 2 and 5 days after ovulation).

Dog sperm can remain viable and fertile within the uterus and uterine tubes for at least 6 days. Therefore it is possible for matings that take place before the fertilization period to result in conception. A second term is therefore used, the fertile period, which encompasses the fertilization period and the time that sperm survive within the female reproductive tract before ovulation and oocyte maturation. The *fertile period* extends from 3 days before until 7 days after the preovulatory LH surge (i.e., between 5 days before and 5 days after ovulation).

The optimal time for mating is during, or immediately preceding, the fertilization period. The period of peak fertility ranges from 1 day before to 5 or 6 days after the LH surge.

252.3.4.2 Determination of the Optimal Time of Mating

252.3.4.2.1 Clinical and management assessments

In laboratory beagles a close association exists between the time of the LH surge and the onset of standing estrus. However, in many breeding bitches a marked variation exists in this relationship, with the LH surge occurring between 3 days before to 9 days after the onset of estrus. Teasing the bitch has little value in determining the fertile period. Assessment of the volume and color of the vaginal discharge is similarly unreliable.

One clinical assessment that may be useful is the timing of vulval softening. During proestrus, the vulva and perineal tissues become enlarged and increasingly turgid in response to increasing estrogen. At the time of the LH surge, serum estrogen concentrations begin decreasing at the same time that serum progesterone concentrations increase. With this change a reduction is seen in edema of the reproductive tract, with the consequence that a distinct softening of the vulva occurs. In cases where only clinical

assessments are available for the determination of the optimum time for breeding, a combination of the onset of standing estrus and the timing of vulval softening may be used. Each of these events occurs on average 1 or 2 days before ovulation. Therefore breeding should be planned commencing on the next day or so for natural mating or commencing 3 days later for preserved semen inseminations.

252.3.4.2.2 Hormone measurement

Measurement of peripheral serum concentrations of LH is a reliable and accurate method of determining the optimum time to mate. However, in many countries it is difficult to obtain reliable LH measures in clinical practice, because enzyme-linked immunosorbent assay (ELISA) kits are not always available. 1683 Serum progesterone concentrations begin to increase toward the end of proestrus at the time of the LH surge. 1684 Luteinizing follicles produce this increase in progesterone; therefore serial monitoring of serum progesterone concentrations allows anticipation of ovulation. Test kits designed to measure progesterone by ELISA are commercially available and have been shown to be useful for predicting the optimum mating time in the bitch. Breeding or insemination should be planned between 4 and 6 days after serum progesterone concentrations exceed 2.0 ng/mL (6.5 nmol/L) (the concentration typically observed at the time of the LH surge). Some reports suggest that breeding should commence 1 day after values exceed 8.0 to 10.0 ng/mL (25.0 to 32.0 nmol/L), which are commonly seen at the beginning of the fertilization period. Progesterone concentration may also be measured in whole blood or vaginal fluid.

252.3.4.2.3 Vaginal cytology

The examination of exfoliative vaginal epithelial cells is frequently used to monitor the estrous cycle. During proestrus, increased serum estrogen concentrations cause thickening of the vaginal mucosa, which becomes a keratinized squamous epithelium. Surface vaginal epithelial cells may be collected using either a moistened swab or by aspiration. The relative proportions of different types of epithelial cells can be used as a marker of the endocrine environment. Several methods for staining of cells and various indices of cornification and keratinization have been suggested. In general, the fertile period can be predicted by calculating the percentage of epithelial cells that appear cornified using a modified Wright-Giemsa stain. Breeding should be attempted throughout the period when more than 80% of epithelial cells are cornified. Although this is a useful guide, some bitches reach peak values of only 60% cornification, and in others there may be two peaks of cornification. Neutrophils are generally absent from the vaginal smear during estrus because the keratinized epithelium is impervious to these cells. Their reappearance during late estrus reflects the breakdown of this epithelium. The return of neutrophils to the vaginal smear has been used by some workers as an indicator of the time of optimum fertility.

Some bitches demonstrate poor cellular changes in the vaginal smear; in some, neutrophils may be found throughout estrus (the extent of these variations has not been quantified). Despite these variations, at the Guide Dogs for the Blind Association in the United Kingdom, mating based on vaginal cytology was found to increase the pregnancy rate and litter size of bitches compared with a similar group mated only based on the onset of proestrus.[9] Whelping rates have been consistently maintained above 90% over a 10-year period since the introduction of this technique.

252.3.4.2.4 Vaginal endoscopy

Endoscopic assessment of the vaginal epithelial contour and profile, mucosal color, and color of any vaginal fluid may be of use for estimating the time of the fertilization period. Enlarged edematous pink

or pinkish-white mucosal folds are present during proestrus and estrus. Progressive shrinking of these folds accompanied by pallor occurs during the preovulatory decline in estrogen. Subsequently, mucosal shrinkage is accompanied by wrinkling of the mucosal folds that become distinctly angulated and dense cream to white in color. These gross changes have been used to assess the fertile period. Jeffcoate and Lindsay[10] proposed a scoring scheme to allow description and recording of the vaginoscopic changes. These clinicians also suggested that vaginoscopy could be used to indicate the end of the fertilization period.

252.3.4.3 Evaluation of Cervicovaginal Secretions

Many workers have reported changes in the nature of the cervicovaginal secretions in relation to the fertile period. These include changes in electrical resistance, glucose concentration, and mucus crystallization patterns. None of these techniques has been subject to detailed validation or widely used in clinical practice.

252.3.5 Normal Estrous Cycle and Copulation (Close to Ovulation) with Conception Failure

252.3.5.1 Infertile Male

An important aspect of infertility is the influence of the male. Poor semen quality can reduce the litter size or result in conception failure. Knowledge of a comprehensive breeding soundness examination of the male is mandatory when investigating a female that might be infertile.

252.3.5.2 Uterine Disease

A common ultrasonographic finding in bitches that fail to become pregnant despite mating to a fertile male during the fertilization period is the presence of cystic endometrial hyperplasia.

Although the exact relationship between this observation and fertility is yet to be proved, the existence of under-lying endometrial disease may contribute to infertility by allowing persistence of commensal bacteria within the uterus (after introduction through the open cervix during estrus) or by interfering with normal placental development. Ultrasonographic detection of cystic endometrial hyperplasia is best achieved during the luteal phase. Cystlike lesions are observed most commonly in middle-aged and elderly bitches and anecdotally may precede the development of later pyometra. Treatment regimes to aid fertility have yet to be fully evaluated.

252.3.5.3 Aplasia of the Tubular Genital Tract

An uncommon cause of infertility is aplasia of one segment of the uterine horn, uterine tube, or both. Frequently this is a unilateral condition that does not influence fertility. Bilateral agenesis is associated with infertility, although the bitch may cycle, ovulate, and mate normally. Diagnosis may be made by positive contrast vagino-uterogram performed during estrus. Laparotomy is a more valuable diagnostic tool.

252.3.6 Normal Estrous Cycle and Copulation with Pregnancy Failure

252.3.6.1 Habitual Abortion

Some clinicians have implicated progesterone deficiency as a cause of repeated abortion in bitches.[11] Despite this contention, the minimum concentration of progesterone in serum required to support the pregnancy is only 2.0 ng/mL.[12] Measurement of progesterone concentration at the time of an abortion often reveals that concentrations are low; however, this is likely to be the result of the abortion rather than the cause of the abortion. Insufficient luteal function has been demonstrated after estrus induction regimens[13] and in one case of oophoritis.[14] Serum progesterone concentrations of bitches with habitual abortion are usually similar to those of normal pregnant bitches. Progesterone or progestogen supplementation during pregnancy may produce masculinized female pups and cryptorchid male pups, and it may possibly impair or delay parturition resulting in fetal death. Progestogen therapy should therefore be restricted to those cases in which a true luteal insufficiency has been diagnosed.

The majority of cases of abortion and resorption may be documented using real-time B-mode ultrasound. In some cases only a single conceptus is lost and the remaining pregnancy continues normally. Most cases of resorption and abortion are related to an abnormal uterine environment (cystic endometrial hyperplasia, see previous discussion), embryonic and fetal defects, or are the result of infectious agents.

1684

1685

252.3.6.2 Infectious Causes of Pregnancy Loss

252.3.6.2.1 Canine herpesvirus

Canine herpesvirus may cause infertility, abortion, stillbirths, and genital lesions in the bitch.[15] In the pregnant bitch, placental lesions and infection of the fetus occurs. Experimental data suggests that infection during early pregnancy results in fetal death and subsequent mummification, infection during midpregnancy results in abortion, and infection during late pregnancy results in premature birth. The virus has also been recovered from vesicular lesions on the genitalia of bitches, and frequently these lesions are evident at the onset of proestrus, suggesting that venereal transmission is probably important. Viral recrudescence from the vesicular lesions may be stimulated by the stress of pregnancy and parturition. Canine herpes virus infection is becoming increasingly recognized within Europe. As a result of this, a vaccine has recently been licensed for use in breeding animals and is commercially available in France and the United Kingdom.

252.3.6.2.2 Brucella canis

This is the only bacterium known to be a specific cause of infertility in the bitch. Infection can produce abortion and infertility. Between 1.5 and 6.6% of dogs in the USA have antibodies to the organism. Brucella can be transmitted by contact with aborted fetal or placental tissue, contact with the vaginal discharge of infected bitches, venereal transmission or congenital infection.

Abortion occurs most commonly between the forty-fifth and fifty-fifth day of pregnancy; however, there may be embryonic resorption or the birth of stillborn or (more rarely) weak pups. The isolation of the bacterium from blood or aborted tissue is diagnostic of the disease; however, there may be prolonged

periods when the bitch is not bacteremic, and a negative blood culture does not rule out infection. Fortunately, diagnosis using the plate agglutination test for screening and tube agglutination for confirmation is not difficult. Treatment of the condition with a combination of streptomycin and tetracycline is often effective in clinical cases; however, antimicrobial treatment does not remove the organism from tissues. Because a carrier state can occur and these animals may be potential sources of infection, they are best neutered and removed from the breeding program.

252.3.6.2.3 Canine adenovirus

It is well established that infection with canine adenovirus during pregnancy can result in the birth of dead or weak pups that die within a few days after parturition. In most cases, however, the virus is ingested after parturition and causes neonatal mortality. Carrier bitches may act as a source of infection for pups.

252.3.6.2.4 Canine parvovirus

Canine parvovirus has been implicated by some breeders as a cause of infertility in their kennels. However, Meunier and colleagues[16] found that the conception rate, incidence of stillbirths, average litter size, or average number of pups weaned per litter did not change after the introduction of canine parvovirus to a kennel. Canine parvovirus may cause an acute generalized infection in pups less than 2 weeks of age, which can occur as a consequence of uterine infection or as a result of exposure to the virus soon after birth.

252.3.6.2.5 Canine distemper virus

Experimental exposure of pregnant bitches to canine distemper virus may produce either clinical illness in the bitch with subsequent abortion or subclinical infection of the bitch and the birth of clinically affected pups. Although the latter provides evidence for transplacental transmission, the frequency of this under natural conditions is unknown.

252.3.6.2.6 Toxoplasma gondii

Toxoplasma infection of the bitch may cause abortion, premature birth, stillbirth, and neonatal death. Surviving infected pups may carry the infection.

252.3.6.3 Normal Vaginal Bacterial Flora

A widespread belief exists among breeders and veterinarians that certain bacteria that inhabit the reproductive tract of the dog and bitch cause infertility, vaginitis, and fading puppy syndrome. This arose from the work in the 1930s that concluded that streptococci were responsible for infertility, abortion, anestrus, and weak pups. With the advent of virus isolation techniques, several specific viruses have been identified, and it seems likely that the earlier work overemphasized the importance of the streptococci. These bacteria are now considered to be part of the normal commensal flora and probably invade secondarily to viral damage or are contaminants.

Many aerobic and anaerobic bacteria normally inhabit the vestibule and vagina of the healthy bitch, and the bacterial flora is normally mixed. The aerobic bacteria isolated from normal bitches include *Escherichia*

coli, staphylococci, and streptococci, whereas the anaerobic bacteria include *Bacteroides* spp. and *Peptostreptococcus* spp. Mycoplasmas have been isolated from between 30% and 88% of normal bitches.

Several authors have examined the vaginal bacterial flora of normal bitches and compared them with those of infertile bitches. These studies were reviewed by van Duijkeren,[17] who found that the bacterial species cultured from infertile bitches did not differ significantly from healthy bitches. Therefore the results of microbiologic examination of the reproductive tract of the bitch must be treated with caution because the simple isolation of bacteria from the vagina does not constitute a diagnosis of reproductive disease. However, disease may result if the uterine or vaginal defense mechanisms are depressed, thereby allowing overgrowth of the normal commensals. Many of the normal vaginal inhabitants may become pathogens if a breakdown in local immunity occurs.

252.4 CONCLUSION

Infertility is an important and increasingly recognized condition in the bitch. Canine female infertility has a number of causes, the most common of which are inappropriate mating time, male factor infertility, and uterine disease. The approach to the infertile bitch should involve a logical investigation to determine the underlying cause, the optimal treatment, and prognosis. After collection of a detailed clinical history and a physical examination, the clinician should determine the typical presentation of the problem, followed by additional investigation to establish the cause. Although specific diseases can be significant causes of infertility, an understanding of the normal anatomy, physiology, and the wide range of variations that can occur is an important aspect of investigating canine female infertility in clinical practice.

253 CHAPTER • 253 Vaginal Disorders

Beverly J. Purswell

253.1 ANATOMY

253.1.1 Embryologic Origins of the Posterior Reproductive Tract

In normal sexual development of female dogs and cats, the urogenital sinus, genital tubercle, and genital swellings become the vestibule, the clitoris, and the vulva, respectively.[1] The paramesonephric (mullerian) ducts give rise to the uterine tubes (oviducts), uterus, cervix, and vagina.[2] The caudal end of the vaginal canal opens into the vestibule by joining the urogenital sinus to the distal paramesonephric ducts at the vaginovestibular junction. Although both the paramesonephric ducts and the urogenital sinus probably contribute to the vaginal epithelium, the vaginal squamous epithelial cells are considered to originate from the urogenital sinus.[2] The urogenital sinus also gives rise to the urinary bladder and to the urethra, which enters the vestibule just caudal to the vaginovestibular junction.

253.1.2 Anatomic Relationship of the Vagina and the Vestibule

The *vestibule* is the common external opening of the urinary and reproductive tracts. Cranially, the vestibule ends at the vagina, where the narrowing of the vaginovestibular junction can be palpated digitally. The vestibule has a distinct ventral slope starting at the vaginovestibular junction and extending caudally to the ventral commissure of the vulva (Figure 253-l). The urethral opening is on the ventral floor of the vestibule approximately 0.5 cm distal to the vaginovestibular junction.

The *vagina* extends (caudal to cranial) from the vaginovestibular junction to the cervix. The bitch has a relatively long vagina, which places the cervix in the abdomen, not the pelvic canal. This length makes examination of the vagina in its entirety difficult without special equipment and impossible using only digital palpation. The anterior part of the vagina is quite narrow (5 to 7 mm), which makes visualization of the cervix and its external os difficult even endoscopically.

253.2 EXAMINATION OF THE VESTIBULE AND VAGINA

253.2.1 Vaginal Cytology

Vaginal cytology is the technique most widely used to evaluate the distal reproductive tract of the bitch and is valuable in the interpretation of the nature of vulvar discharges. Localization of a disease process may be facilitated by comparing cytology from the vestibule to that of the vagina. Vaginal cytology is indicated any time disease of the reproductive tract is suspected.

Neutrophils in low numbers are seen normally in vaginal cytology at any time except during the peak of the estrogenic phase of the estrous cycle (middle to late proestrus and all of estrus). Large numbers of neutrophils are seen in early diestrus; this influx of neutrophils is not associated with any disease process and is considered a normal phenomenon. The presence of large numbers of neutrophils during any other stage of the estrous cycle indicates an inflammatory process.

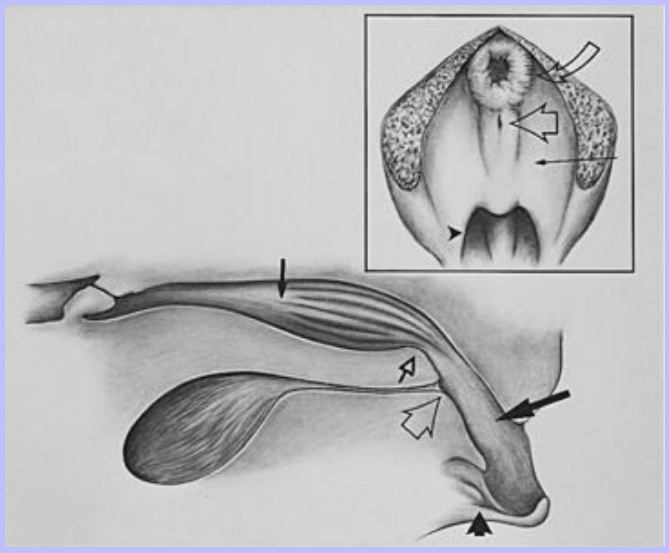
253.2.2 Visual and Digital Examination of the Vagina and Vestibule

Digital examination of the distal reproductive tract is valuable in the diagnosis of a variety of abnormalities. However, the animal's size may limit the examination. Because of the length of the distal reproductive tract, particularly that of the vagina, it is impossible to examine the vagina digitally in its entirety. Only the vulva, vestibule, urethral opening, and vaginovestibular junction can be adequately evaluated with a digital examination. Many of the abnormalities found in this area are best diagnosed with a digital examination and may remain undetected with other forms of inspection.

Vaginoscopy may be performed with an endoscope, a proctoscope, or any fiber-optic equipment long enough (15 to 20 cm) to allow inspection of the entire vagina. The procedure can be performed on the awake, standing bitch with sedation used as needed. Rigid equipment (e.g., proctoscope) tends to allow better visualization of the vagina than the flexible endoscopes because of the collapsing nature of the vaginal folds. When flexible fiber-optic endoscopes are used, insufflation of the vagina with air is necessary for a thorough examination. 1686

The outside diameter of the endoscope must be 5 mm or less for complete visualization of the anterior vagina and paracervical area.[3] This small diameter may also be helpful for traversing the narrowing at the vaginovestibular junction for examining small bitches (those weighing less than 9 kg). Body size does not always correlate with the vestibular and vaginal diameter, especially in the prepubertal or ovariectomized bitch. Equipment less than 5 cm in length (e.g., otoscopes) provide visualization only of the vestibule. 1687

Figure 253-1 Anatomic relationship of the vestibule and the vagina in the bitch. The insert shows the annular stricture at the vaginovestibular junction cranial to the urethral opening. Other structures shown are the urethral opening *(open arrow head),* the clitoral fossa *(solid arrow head),* the vaginovestibular junction *(open arrow),* the vagina *(solid arrow),* and the vestibule *(large solid arrow).*



253.2.3 Vaginal Bacterial Cultures

It has become common practice for clients to request vaginal cultures from bitches prior to breeding. The literature includes reports on vaginal flora in normal bitches and bitches with reproductive tract disease.[4,5] The species of bacteria isolated from the cranial and caudal vagina are similar in these two groups. The aerobic bacterial flora of the bitch's vagina consists of common opportunistic pathogens, the presence of which does not influence fertility.[5] Careful interpretation of culture results is mandatory in the evaluation of an area with normal flora. Culture of the vagina during an overt disease process is valuable in the selection of appropriate therapy. However, isolation of opportunistic aerobic pathogens, anaerobic bacteria, or mycoplasmas in an asymptomatic animal does not constitute evidence of infection.[4] Research shows that prophylactic use of antibiotics in apparently healthy breeding bitches may predispose the vagina to colonization by organisms that are known opportunistic pathogens.[6] Only a guarded swab technique should be used to obtain vaginal cultures.

253.3 VAGINAL ABNORMALITIES

253.3.1 Vaginitis

The term *vaginitis* describes an inflammatory process, not necessarily an infectious one. Inflammation can be identified easily with vaginal cytology and vaginoscopy. The clinical signs are those associated with irritation, such as licking, vulvar discharge, and attraction of male dogs. With vaginitis, vaginal cytology shows increased numbers of neutrophils in various stages of degeneration, with or without increased numbers of bacteria. Chronic vaginitis may induce the presence of lymphocytes and macrophages. Vaginoscopy reveals the presence and extent of hyperemia, exudate, and mucosal lesions, such as vesicles, ulcers, and lymphoid follicle hyperplasia. An attempt should be made to differentiate other systemic disorders that cause similar signs. Urinary tract problems should be ruled out as a cause of the vestibular irritation or attraction of male dogs. Lymphoid follicle hyperplasia is a common finding in the vestibule of bitches with urinary tract infections arising from chronic inflammation. Dermatologic lesions may be the cause of a perineal irritation and can prompt excessive licking. Comparison of vestibular cytology with vaginal cytology may aid in localization of the problem.

Juvenile (puppy) vaginitis is a common malady in prepubertal bitches. The most common sign is purulent vulvar discharge. Juvenile vaginitis may respond to systemic antibacterial therapy or to topical douching, but inevitably the signs return when treatment is discontinued. The condition resolves naturally after the first estrous cycle, if not before. Neutering of these animals should be postponed until signs have resolved or the first estrus has occurred. The vulvar area should be kept clean to prevent secondary skin problems. No other treatment is necessary.

Adult vaginitis can be caused by anatomic abnormalities that lead to accumulation of discharge or urine in the vagina. Accumulation of urine in the vagina may cause apparent urinary incontinence, with urine dribbling from the vulva when the bitch changes position. Bacterial or chemical vaginitis occurs secondary to the predisposing cause.

Strictures at the vaginovestibular junction are thought to cause problems in some individuals. Care must be taken to localize the area of inflammation before this diagnosis is made. These vaginovestibular strictures can be easily identified by a digital examination. Digital or surgical dilatation may be required to eliminate the problem, although recurrence is common. Vaginectomy may be required in persistent cases. Vaginoscopy,

contrast radiography, or other imaging modalities should be used to rule out foreign bodies, tumors, and uterine stump granulomas as predisposing causes (Figure 253-2). Contrast radiography may be helpful in identifying anatomic abnormalities or concurrent urinary tract disease, including acquired ectopic ureters after ovariohysterectomy.[7] A knowledge of the normal changes that occur in the vagina with the estrous cycle is critical in the interpretation of contrast radiographs (Figure 253-3). When vaginoscopy is performed in an animal with chronic inflammation, care must be taken not to perforate the vaginal wall.

Because systemic disease may predispose a bitch to vaginal infection, the animal's general health should be evaluated. If a predisposing cause is not identified, vaginal cultures should be performed and appropriate antibacterial therapy instituted. In some cases of chronic inflammation without any apparent predisposing cause, glucocorticoids may be useful for eliminating the inflammation. Initial lavage of the vagina may be beneficial for removing accumulated material.

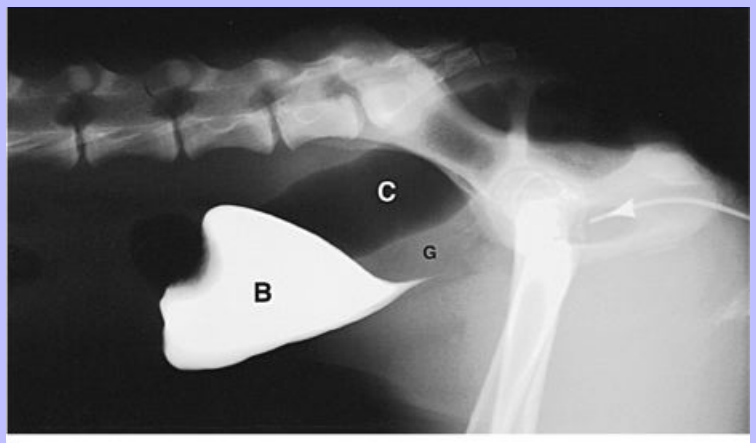
Viral vaginitis has been described in conjunction with canine herpesvirus infection. Genital infections of canine herpesvirus result in diffuse, multifocal, raised vesicular lesions on the vaginal mucosa that characteristically cause no clinical signs in the bitch.[8] No treatment is necessary, but it is advisable to separate the affected animal from any pregnant bitches or neonatal puppies.[9]

253.3.2 Anatomic Abnormalities

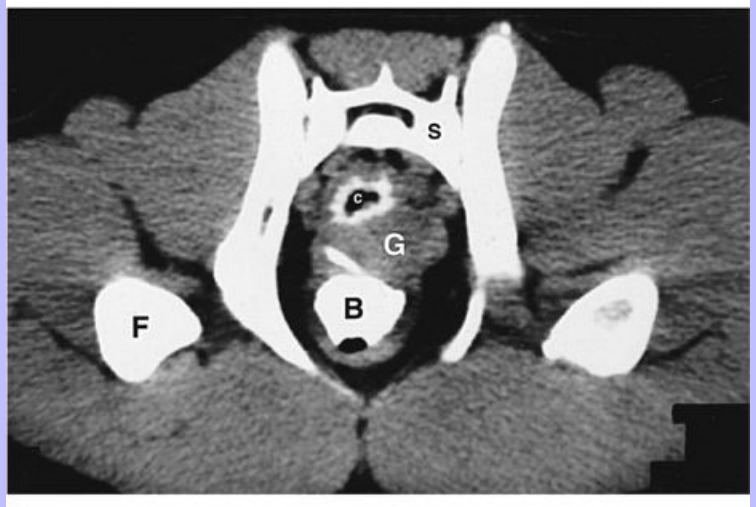
A variety of congenital abnormalities of the vagina and vestibule have been described. The exact incidence is unknown, but some of these abnormalities are common. Abnormal embryologic development is responsible for most of these conditions.

A persistent hymen occurs at the junction of the vagina and vestibule where the paramesonephric duct joins the urogenital sinus. Incomplete perforation of the hymen usually causes an annular stricture (see insert in Figure 253-1) or a vertical septum or band. Affected bitches most often have breeding difficulties, chronic vaginitis, or urinary incontinence unresponsive to conventional therapy because of urine pooling. Digital palpation is the preferred method of diagnosing these conditions. Vaginoscopy may bypass the affected area. If these anomalies are incidental findings in an asymptomatic animal, no correction is necessary. Digital dilatation can be attempted in either condition and may be successful, depending on the extent of the tissue involved. An episiotomy may be required to attain adequate exposure of the vaginovestibular junction for surgical manipulation. A vertical band is easily removed surgically, and correction of the presenting signs is usually complete. An annular stricture is more difficult to correct permanently. The stricture may be excised completely, with the mucosa closed perpendicular to the initial incision, in an attempt to enlarge the lumen. Another approach is to make a series of radial incisions perpendicular to the lumen. Both procedures may require frequent and repeated postoperative digital dilatation to prevent stricture recurrence. Clinical signs may persist after attempted surgical correction. Vaginectomy is an alter-native therapy that alleviates problems associated with the vagina.

Figure 253-2 Uterine stump granuloma in a 7-month-old spayed bitch presented for urinary incontinence. **A,** Lateral abdominal radiograph obtained after infusion of air into the colon *(C)* and iodinated contrast medium into the urinary bladder *(B)*. The uterine stump granuloma *(G)* is evident as a soft tissue mass compressing the neck of the urinary bladder. **B,** Transverse computed tomographic image obtained at the level of the cranial pelvic canal (sacrum *[S]* and femur *[F]*). The granuloma is compressing the left ureter at the trigone and indenting the left dorsolateral margin of the urinary bladder. (Courtesy Dr. Jeryl C. Jones, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, VA.)



A



B

Bitches with annular strictures may be bred artificially and re-evaluated immediately prior to parturition. Sufficient relaxation usually occurs to allow normal delivery of the puppies. Cesarean section or an episiotomy may be needed at parturition if relaxation is insufficient to allow whelping.

Vaginal anomalies arise as a result of problems associated with organogenesis of the paramesonephric duct. The external genitalia and vestibule are usually normal in these animals because of their separate embryologic origin. Incomplete fusion of the paramesonephric ducts results in a vertical septum in the vagina (double vagina).[10] Surgery is indicated if the bitch's intended use is breeding or if clinical signs are present. Concomitant anomalies must be ruled out prior to attempted correction of any abnormality. Segmental hypoplasia or aplasia of the vagina has been described in the bitch, and surgical correction is not possible. Vaginal diverticula may occur and can fill with debris, causing local inflammation. Surgical removal of the diverticula is indicated to resolve this condition. Contrast radiography and vaginoscopy are helpful in identifying and defining the extent of the various vaginal anomalies. Ovariohysterectomy may be indicated when the condition is extensive. A partial or total vaginectomy may also be indicated when the condition is causing secondary problems, such as chronic urinary tract infections.

Vulvar anomalies are occasionally identified in a bitch with breeding difficulties. Tight bands at the dorsal commissure are a common cause of painful copulation (dyspareunia) and are easily identified with digital palpation. If necessary, the bitch may be bred artificially and re-examined immediately prior to parturition to assess potential whelping difficulties. Relaxation of the vulva is usually sufficient to allow normal delivery.

Inverted vulvas may be found in prepubertal bitches. The vulva is inverted to the point of being hidden from view by skin folds. Vaginitis, perivulvar irritation, vulvar discharge, or urinary tract disease may occur secondary to the infolding of the vulva and distortion of the vestibule and urethral opening. Neutering of these bitches should be postponed until after the first estrus. Eversion of the vulva normally occurs during the first estrus, and the condition is self-correcting. In bitches neutered prior to puberty, episioplasty may be necessary to alleviate the chronic urinary tract infections and perivulvar dermatitis associated with an inverted infantile vulva.[11,12] Removal of the redundant skin folds around the vulva exteriorizes the vulva, which helps eliminate the perivulvar dermatitis. Exteriorization of the vulva results in less turbulence of urine during voiding, making ascending infections less likely (Figure 253-4).

Faulty urogenital sinus embryogenesis may lead to congenital problems in the vestibule, vulva, and perineum. Open vulvar clefts, perineal dysgenesis, and rectovaginal fistulas have been described in the bitch and require surgical correction. These distal abnormalities, which can be acquired or congenital, may be associated with other reproductive or urinary tract anomalies. Clitoral anomalies are usually associated with intersex conditions and take the form of clitoral enlargement with penislike anatomy (Figure 253-5). Surgical removal of the clitoris to prevent excoriation is advised if the clitoris protrudes from the vulva.

Figure 253-3 Variations in the normal appearance of the canine vagina after retrograde positive contrast vaginography. **A,** Anestrus. Note the smooth mucosal margination and absence of filling defects, as well as the closed cervix, which allows no contrast medium to ascend into the uterus. **B,** Estrus. Note the thickened rugae appearing as linear filling defects in the mucosal margins and the open cervix, which allows contrast medium to ascend into the uterus. (Courtesy Dr. Jeryl Jones, Virginia-Maryland Regional College of Veterinary Medicine, Blacksburg, VA.)

253.3.3 Vaginal Fold Prolapse, Vaginal Hyperplasia, and Vaginal Prolapse

Under the influence of estrogen, some young bitches develop an edematous ventral fold in the distal vaginal mucosa immediately cranial to the urethral opening (Figure 253-6); this fold may become large enough to protrude from the vulvar opening. Traditionally, this condition has been referred to as vaginal hyperplasia. Histologically, however, this tissue is no more hyperplastic than the rest of the vagina under the influence of estrogen. Pronounced edema is the major histologic lesion, with fibroplasia resulting from the edema. Prolapse of a vaginal fold occurs almost exclusively when the bitch is under the influence of estrogen; this may occur at

the first estrus or become evident during later estrous cycles. Once the condition manifests itself, it has a tendency to recur during each subsequent estrus. The condition usually is self-limiting and resolves once the estrogenic influence ends at the onset of diestrus or with ovariohysterectomy. Ovariohysterectomy resolves the condition permanently and is the treatment of choice for animals not intended for breeding. Surgical removal of the prolapsed tissue can be attempted and resolves the condition permanently in some animals. Artificial insemination can be performed in affected bitches, with resolution expected with the onset of diestrus. Occasionally vaginal fold prolapse fails to resolve after estrus, or it recurs at the end of pregnancy, when estrogen levels rise slightly.[13] The condition is not generally thought to be hereditary, although evidence indicates a hereditary predisposition in some family lines and some breeds.

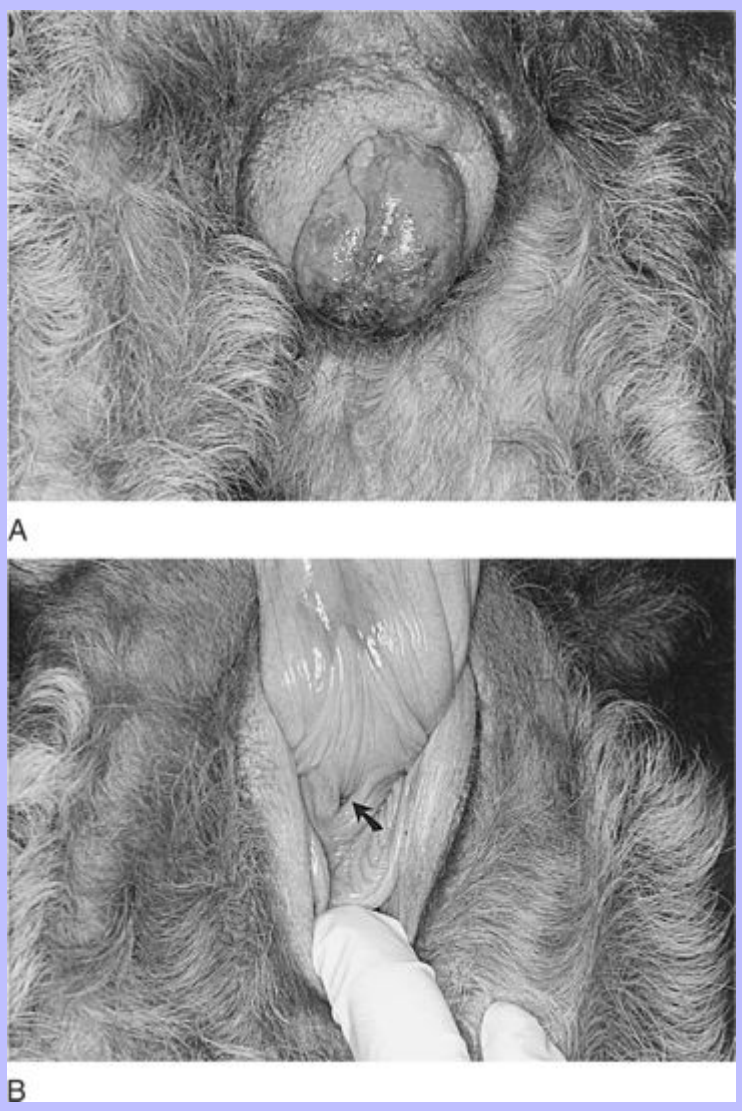
Figure 253-6 Vaginal fold prolapse (vaginal hyperplasia) in a bitch. **A,** Vaginal fold prolapse protruding from the vulva; excoriation is evident. **B,** Vaginal fold prolapse originating anterior to the urethral opening (arrow indicates urethral opening).



253.3.4 Miscellaneous Vaginal Disorders

Vaginal lacerations can occur during copulation, obstetric procedures, or vaginoscopy. Hemorrhage from the vulva is the primary sign. A bitch that bleeds from the vulva after breeding should be examined for vaginal

tears. The decision must be made whether suturing is necessary or possible. Systemic antibiotics should be administered to prevent infections, particularly dissecting pelvic infections.

Vaginal and vulvar neoplasia account for 2.5% to 3% of all canine tumors[14]; 70% to 80% of these tumors are benign. Signs may include perineal enlargement, a mass protruding from the vulva, vulvar discharge, tenesmus, or dysuria. Tumors prolapsing from the vulva must be differentiated from vaginal fold prolapse through evaluation of the stage of the estrous cycle and its relationship to the onset of signs, the location of the mass, and failure of the mass to regress at the onset of diestrus. Leiomyomas are the most common benign tumor and are often pedunculated. Leiomyosarcoma is the most common malignant vaginal tumor. Surgical excision is the treatment of choice for tumors. Transmissible venereal tumors are more common in younger animals and respond readily to chemotherapy. The prognosis for vaginal and vulvar tumors is good provided metastasis has not occurred with the malignant tumors. Ovariohysterectomy is recommended at the time of removal because of the possibility of hormonal influence on the incidence and possible recurrence rate.

Vaginal prolapse rarely occurs in the bitch or queen. It is usually associated with dystocia, tenesmus, or forced extraction of the male during the genital tie in the dog. Uterine prolapse may follow, depending on the cause. Treatment involves replacement of the affected structures. An abdominal approach may be necessary to replace the vagina. An ovariohysterectomy may be performed at the time of correction if so desired.

254 CHAPTER • 254 Semen Evaluation, Canine Male Infertility, and Common Disorders of the Male

Mushtaq A. Memon

Kaitkanoke Sirinarumitr

254.1 SEMEN EVALUATION

The purposes of semen collection and evaluation are to assess an animal for breeding soundness; to perform artificial insemination; to preserve semen; to attempt to localize the site of disorder in some infertile dogs; and to determine treatment response for infertile dogs. Collection of the prostatic fluid and its submission for cytology and bacterial culture may help differentiate prostatic disorders from other problems. Semen evaluation may be performed before a dog is purchased, before he is first used for breeding, or if he shows signs of infertility. Semen collection and evaluation are relatively easy and can be done at any small animal practice. The results should be recorded on the canine Breeding Soundness Examination (BSE) form, which was devised by the Society for Theriogenology.

254.1.1 Semen Collection

254.1.1.1 Equipment

Semen from the dog is easily collected using an artificial vagina (AV), a device composed of a latex rubber cone (Reproduction Resources, Hebson, Illinois) connected to a 15 mL calibrated plastic centrifuge tube. The AV should be washed with plain tap water (no soap, detergent, or other cleansing agent is used), rinsed thoroughly with distilled water, and air dried. Gas sterilization, if available, may be used on the AV. Some dogs may ejaculate into other containers under the pressure of hand massage alone. However, semen is collected successfully from most dogs with an AV because the AV simulates the pressure normally felt by the male during copulation. The calibrated collection tubes used in the procedure should also be washed with tap water, rinsed with distilled water, and sterilized with gas or autoclaved before use to prevent the formation of formaldehyde residues, which are harmful to sperm.[1]

For optimum results, collection should be done in a quiet room with the dog on a nonslip surface and with the owner present. Semen may be collected before other examinations are performed, including the physical examination. For better responsiveness, the semen can be collected in the presence of a teaser bitch in proestrus or estrus. If a bitch in estrus is not available, a commercially available pheromone (Eau d' Estrus, International Canine Genetics, Malvern, Pennsylvania; or methylparaben; Sigma Chemical, Saint Louis, MO) or vaginal swabs from a disease-free estral bitch can be used. The top of the AV should be folded down, and a scant amount of lubricant should be applied to facilitate later removal of the device from the dog's erect penis.

254.1.1.2 Procedure

The male and female are brought on leashes into a collecting room and allowed to play for a few minutes. The semen collector, if right handed, kneels at the dog's left side and, holding the AV in the left hand, uses the right hand to move the prepuce up and down the penile shaft to achieve protrusion of the penis into the

AV. (Left-handed collectors may reverse the sides described above.) As the male begins to thrust the penis into the AV, the collector moves the sheath above the engorging bulbous glandis, keeping firm, steady pressure around the circumference of the penis to maintain the erection (Figure 254-1). Most male dogs ejaculate the presperm (clear) and sperm-rich fractions (cloudy) of the semen during pelvic thrusting; they then dismount and lift one hind leg as though trying to step over the bitch and achieve the tie. At this point the penis should be rotated 180 degrees, so that it is directed caudally, and held still, with tight pressure maintained around the circumference, until the third prostatic fraction of semen has been ejaculated. The prostatic fluid is ejaculated after a short pause in association with anal contractions and rhythmic pulsations of the penile urethra, which the collector can detect. After a few milliliters of prostatic fluid have been collected, the AV may be removed from the penis; the dog may continue to ejaculate prostatic fluid for some time after removal of the AV. The dog should not be kenneled or sent home until the erection has subsided completely and the entire penis is back in the preputial sheath. Normally, this takes about 5 to 10 minutes after semen collection.

254.1.2 Evaluation

Five parameters, in particular, should be evaluated and recorded for each semen collection (Table 254-1): the color and volume of the sample, and the motility, concentration/total number, and morphology of the sperm.

Figure 254-1 Latex rubber cone (artificial vagina) fitted over the penis during semen collection.

254.1.2.1 Color

The color of the sample is observed grossly in the collection tube. The first fraction should be clear, whereas the second (sperm-rich) fraction should be milky white. The third fraction (prostatic fluid) should be clear. Yellow discoloration may indicate urine contamination or the presence of purulent exudate. A red or brown color may indicate prostatic disease, trauma, urethritis, or ulceration.

254.1.2.2 Volume

The volume of semen can be read directly from the calibrated collecting tube. Volume varies among breeds and among individual dogs. Semen volume is not an important parameter with regard to the BSE, but it is necessary for determining the number of sperm per ejaculate. The separate volume for the prostatic fluid need not be recorded, because it varies according to the length of time the prostatic fluid is collected.

254.1.2.3 Sperm motility

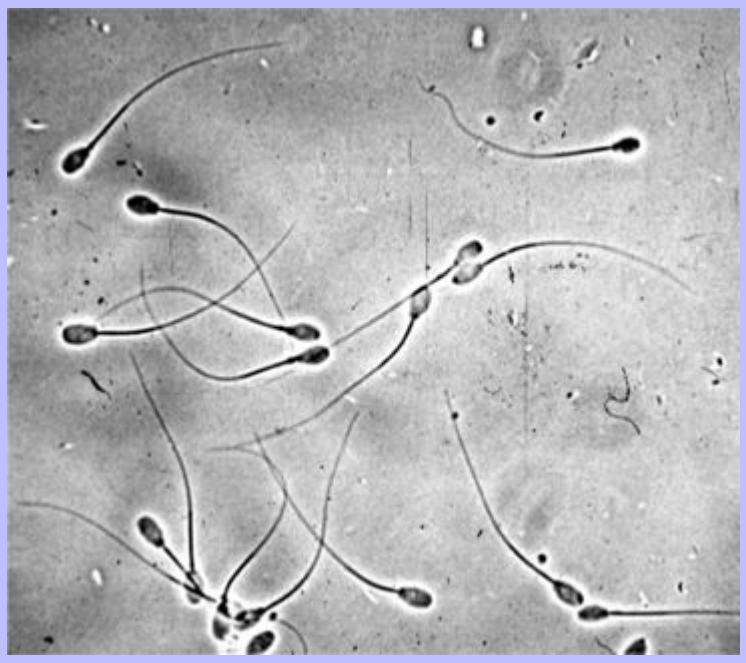
Motility testing should be performed immediately after collection. The examiner places a drop of undiluted semen on a slide with a cover slip, examines the specimen at ×100 to ×200 magnification (because canine spermatozoa are resistant to cold shock, the slide need not be warmed), and estimates the percentage of sperm cells moving in a progressive and forward manner across the field (Figure 254-2). Although sperm motility estimation is not precise, it is a quick functional test.

1691 1692

Table • 254-1 Characteristics of Normal Canine Semen

		SEMINAL FRACTION		
PARAMETER	UNFRACTIONED EJACULATE	1	2	3
Color	Opaque to white	Clear	Milky white	Clear
Volume (mL)	~30	0.1–2	0.1–4	1–25 +
pH	6.1–7.0	6.2–6.4	–	–
Sperm motility	>80 %	–	–	–
Morphologically normal sperm	>80 %	–	–	–

Figure 254-2 Estimation of the percentage of motile sperm (i.e., those moving in a progressive, forward manner) in a semen sample.



254.1.2.4 Concentration/total number of sperm

The total number of sperm in the ejaculate is more important than the concentration of sperm per milliliter, because the concentration changes dramatically depending on the amount of prostatic fluid collected. The sperm concentration can be measured with a commercial WBC Unopett system (Becton Dickinson, Rutherford, New Jersey) (Figure 254-3). The semen sample is stirred gently, drawn up into the capillary pipette (20 μL) provided with the kit, and dispensed into the diluent-containing reservoir chamber. Diluted semen then is dispensed into both chambers of a Neubauer hemocytometer (Becton Dickinson, Rutherford, New Jersey) (Figure 254-4), and the contents of the grid's 1-mm central square (composed of 25 small squares) are counted on each side of the hemocytometer and averaged.[2] (The central square fills the field of a light microscope when the ×10 objective is used.) The number of spermatozoa in the central square is the concentration in millions of spermatozoa per milliliter of semen. The total number of sperm in the ejaculate equals the concentration multiplied by the volume. The normal total number of sperm[1] ranges from 300 to 2000×10^6; large breed dogs ejaculate more sperm than small breed dogs.[3] (Direct cell counts done with the hematocytometer are time-consuming; quicker methods used to determine the sperm concentration are an electronic blood cell counter or spectrophotometer.) The total number of sperm may be decreased in quite young, old, and inbred dogs.

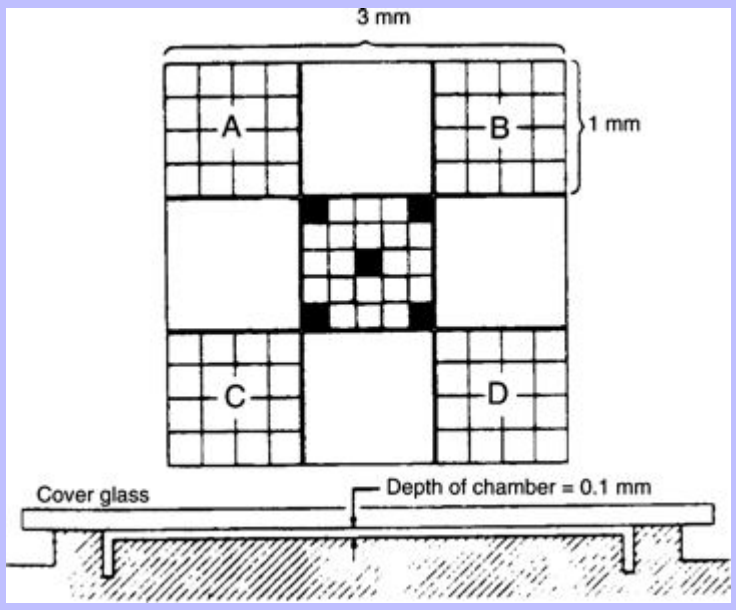
254.1.2.5 Sperm morphology

Sperm morphology is usually assessed by staining the semen sample and observing the sperm under oil immersion (×1000) objective. Various stain techniques may cause some artifactual changes in sperm morphology. Defects vary with the stain used, but the percentage of morphologically normal sperm should be fairly consistent regardless of method.[4] Eosin/nigrosin stain and Wright's Giemsa stain (Diff Quik) are the stains most commonly used. For staining with eosin-nigrosin, a drop of semen and a similar-sized drop of stain are placed on one end of a clean glass slide and mixed gently with a wooden applicator. A second slide then is used as a spreader slide. A thin film, similar to a blood smear, is made and air-dried. For staining with rapid Wright's Giemsa stain, the semen smear is made as for a blood smear, air-dried, and immersed in each of the three solutions for 5 minutes each. The slide then is rinsed and allowed to dry. One hundred sperm cells should be examined and the findings recorded, including normal sperm, primary abnormalities (all head defects, proximally coiled tails, proximal cytoplasmic droplets), and secondary abnormalities (detached heads, bent tails, and distal cytoplasmic droplets). Primary abnormalities are abnormalities that occur in the testis during spermatogenesis. Secondary abnormalities occur during epididymal transport or as a result of sample-handling techniques. Most dogs have greater than 80% normal sperm per ejaculation.[5]

Figure 254-3 WBC Unopett system, used to measure sperm concentration.

1692

Figure 254-4 Neubauer hemocytometer, which is used to count sperm.



254.2 CANINE MALE INFERTILITY

Infertility in the male may result from infections, endocrinopathies, structural abnormalities, neoplasia, illness, or poor breeding management. Abnormalities of the genital tract, which includes the penis, prepuce, testes, epididymis, vasa deferentia, urethra, and prostate gland, may also result in infertility. These conditions may result in reduced libido or failure to achieve normal copulation. A thorough physical examination should be conducted after semen is collected.

254.2.1 History

A complete medical history of the male dog should be obtained, including information on vaccinations, diet, medications, past illnesses, and laboratory results, as well as a complete reproductive history. The record also should include a list of all breedings; the litter size from each breeding; the results of previous semen evaluations; and the breeding history of each bitch, including her estrous cycle, progesterone level, and conception rates from breedings with other males.

254.2.2 Physical Examination

A thorough physical examination should be performed. Abnormalities that may interfere with libido or ability to mount and achieve intromission include a persistent frenulum, hypospadias, disk disease, spondylosis, hip dysplasia, and a luxating patella. Dogs with heritable diseases should not be bred. The penis and prepuce should be inspected and palpated for any abnormalities. The erect penis can be examined after semen collection.

The scrotum and testes should be palpated for consistency and shape. Testicular degeneration, hypoplasia, or atrophy may result in softening of the testis, whereas testicular fibrosis or neoplasia may result in hardness of the testis. Although testicular size varies normally among breeds, the size should be measured with calipers and recorded. An abnormally enlarged scrotum or testis may indicate inflammation. Each epididymis, including the head, body, and tail, should be thoroughly palpated and the results recorded.[5]

The prostate is the major accessory sex gland and is responsible for seminal volume. It is an encapsulated, bilobed, bilaterally symmetric ovoid gland, located at the caudal pole of the bladder, that encircles the proximal urethra.

The prostate should be palpated by digital rectal examination after semen has been collected.

254.2.3 Additional Diagnostic Tests

Infertile dogs may require additional tests, including determination of the seminal plasma pH; aerobic and anaerobic bacterial cultures; culture for mycoplasmas and ureaplasmas; and semen cytology. Seminal fluid from samples that lack sperm should be evaluated for its alkaline phosphatase (ALP) concentration, which comes from the epididymis, to ensure a complete ejaculation.[2] Hormonal assays and epididymal aspiration, testicular biopsy, and chromosomal karyotyping may be considered in dogs with azoospermia. Ultrasonographic examination is a useful diagnostic procedure for detecting some abnormalities of the prostate, testes, and epididymis.

254.2.4 Azoospermia

Azoospermia is the ejaculation of seminal plasma without spermatozoa.[6] The causes of azoospermia may be classified as pretesticular, testicular, and post-testicular. Pretesticular causes in dogs include hypopituitarism, long-term high-dose steroid or antineoplastic therapy, hypothyroidism, inguinal and scrotal hernia, and fever. Testicular causes include intersex, germinal cell aplasia, bilateral cryptorchidism, testicular injury, irradiation, orchitis, autoimmune testicular disorders, and testicular neoplasia.[2,7] Phenotypic male dogs with chromosome abnormalities such as XXY or XX-male syndrome usually have aspermatogenesis. In dogs, XXY karyotype usually causes testicular hypoplasia and hypoplasia of tubular and accessory reproductive organs, along with azoospermia and sterility. Post-testicular causes of azoospermia include obstruction of the collecting ducts, epididymides, or ductus deferens, including epididymal segmental aplasia; sperm granulomas; spermatocele; acute inflammation; neoplasia; and previous vasectomy.[9] Some dogs may have azoospermia as a result of incomplete ejaculation.

254.2.4.1 Incomplete Ejaculation

Incomplete ejaculation may occur in normal, intact dogs that require the presence of a bitch in proestrus or estrus during semen collection. Some nervous or inexperienced dogs may also have an incomplete ejaculation. The dog may ejaculate only presperm fluid. More than one sample should be collected and evaluated before a diagnosis of azoospermia is made. Seminal fluid should be submitted for ALP measurement. The concentration normally is less than 5000 U/L for dogs that failed to have a complete ejaculation. Dogs with true azoospermia arising from causes other than bilateral blockage of the outflow tract usually have a seminal ALP concentration greater than 5000 U/L. If the seminal ALP concentration is

equivocal, another semen collection should be performed and the sample submitted for seminal ALP determination.[2]

254.2.5 Oligospermia

The term *oligospermia* refers to a low total number of spermatozoa in the ejaculate. Oligospermic dogs are not necessarily infertile. Causes of oligospermia reported in dogs include unilateral Sertoli cell tumor, orchitis, epididymitis, prostate diseases, incomplete ejaculation, retrograde ejaculation, overuse, and partial outflow obstruction.[2,9] Reported infectious causes of orchitis and epididymitis in dogs include *Brucella* sp., *Escherichia coli,* mycoplasma, and other aerobic organisms that make up the normal preputial flora.[2] Retrograde ejaculation has been reported in dogs.[10] The diagnosis of retrograde ejaculation may require collection of urine by cystocentesis after ejaculation and comparison of the number of sperm in the ejaculate with the number in the urine sediment. Retrograde flow of semen has been demonstrated in dogs sedated with xylazine.[11] Dogs with idiopathic oligospermia may be treated with a gonadotropin-releasing hormone (GnRH) agonist (1 µg/kg given subcutaneously), with or without subsequent treatment with human chorionic gonadotropin (HCG) (1600 IU given intramuscularly).

1693

1694

254.2.6 Teratozoospermia and Asthenozoospermia

The term *teratozoospermia* refers to a low percentage of morphologically normal sperm (greater than 80% of sperm should be morphologically normal). Congenital causes of teratozoospermia in dogs include fucosidosis, a lysosomal storage disease that affects epididymal epithelial cell function, causing the retention of cytoplasmic droplets. Acquired causes reported are testicular tumors; orchitis; prostatitis; high fever; and obesity, which causes an increase in the intrascrotal temperature due to periscrotal fat. The causes of asthenozoospermia (progressive sperm motility less than 70%) are the same as those for teratozoospermia, as well as infection of the reproductive tract, use of contaminated collection equipment, and immotile cilia syndrome. Water-soluble lubricants, residues from the manufacture of latex or plastic AVs or collecting tubes, urine, and water can reduce the motility of sperm.[2,9] Sperm agglutination and reduced motility may be found in dogs that test positive for *Brucella* infection.

254.3 COMMON DISORDERS OF THE MALE DOG

254.3.1 Benign Prostatic Hypertrophy

Benign prostatic hypertrophy (BPH) is a naturally occurring, age-related condition in men and intact dogs. Most dogs with BPH are over 5 years of age. Dogs with BPH are predisposed to prostatic cysts, infections, and prostatic abscessation. An enlarged prostate may compress the descending colon or the rectum, or both.[2]

254.3.1.1 Pathogenenesis

The pathogenesis of BPH is not completely known. Dihydrotestosterone (DHT), testosterone, estradiol, and some growth factors are involved in prostatic growth.[12] The hormone DHT, a metabolized form of testosterone, plays a major role in the growth of both the stromal and glandular components of the prostate.[13]

254.3.1.2 Clinical Signs and Diagnosis

Clinical signs of BPH include constipation, dripping of a sanguineous discharge from the tip of the penis, blood-contaminated urine or semen, and difficulty urinating.[13] Dogs with BPH may or may not show any clinical signs related to BPH. Diagnosis of BPH requires determination of prostatic enlargement that is not caused by any other prostatic diseases. The prostate gland of dogs with BPH is symmetrically enlarged and moderately firm, and no signs of pain are associated with rectal palpation.[14] Dogs with BPH that also have a prostatic cyst may have asymmetrically shaped prostatic lobes.

Ultrasonographic examination demonstrates symmetrically enlarged prostatic lobes. The prostatic parenchyma is homogeneous in echogenicity with or without a cavitating cystic lesion. On radiographic films, enlargement of the prostate is suggested if the prostatic diameter on lateral radiographs is greater than 70% of the distance between the sacral promontory and the pubis.

Prostatic volume can be predicted using the following formula:

$$[1/2.6\ (L \times W \times D)] + 1.8$$

where *L* is the greatest craniocaudal measurement, *W* is the transverse measurement, and *D* is the dorsoventral measurement of the prostate, as measured using ultrasonography.[15] The results of a complete blood count in dogs with BPH are normal, and aerobic bacterial culture of prostatic fluid shows less than 10,000 colony-forming units (CFU) per milliliter.[13]

254.3.1.3 Treatment

The treatment goals for dogs with BPH are to reduce the size of the prostate and alleviate the signs related to BPH. In most dogs, castration is recommended for BPH. Medical treatment is suitable for valuable breeding dogs and for dogs with a high risk of adverse reactions to anesthesia or surgery. The recommended drug for BPH treatment is finasteride (Proscar), administered at a dosage of 0.1 to 0.5 mg/kg (or 1 tablet/dog weighing 1 to 50 kg), given orally every 24 hours for 1 to 4 months.[13] In dogs with BPH that were treated with finasteride, the prostate became involuted through programmed cell death, or apoptosis, rather than necrosis, therefore no inflammatory process arose in the involuted prostate.[16] Finasteride reduces prostatic volume and the serum DHT level but does not adversely affect the semen quality, libido, serum testosterone concentration, or fertility.[13,17,18]

254.3.2 Prostatitis

Bacterial prostatitis is common in sexually intact dogs and can be acute or chronic. The organism most commonly found in dogs with prostatitis is *E. coli,* followed by staphylococci and streptococci.[19]

254.3.2.1 Clinical Signs and Diagnosis

Clinical signs in dogs with acute prostatitis include fever; pain; depression; straining to urinate or defecate; stiff-legged gait; hematuria; edema of the scrotum, prepuce, or hindlimb; and pollakiuria. During rectal examination of the prostate, dogs with prostatitis show signs of pain. The prostate may be asymmetric if

abscessation is present. Dogs with chronic prostatitis may have clinical signs of infertility problems or lower urinary tract disease.[2] Dogs with prostatitis may have leukocytosis. The urine may contain blood, bacteria, and white blood cells. Prostatic fluid collected either by ejaculation or by prostatic massage contains a significant number of inflammatory cells, and the aerobic bacteria count is greater than 10,000 CFU/mL.[2] Prostatic abscesses detected by ultrasonography are usually discrete, hypoechoic or anechoic lesions with or without distant enhancement.

254.3.2.2 Treatment

Prostatitis with abscessation can be treated medically and/or surgically. Surgical correction of prostatic abscessation may be associated with a high percentage of adverse sequelae. Surgical techniques used include marsupialization, placement of a Penrose drain, drainage with omentalization of the cavities remaining, and partial prostectomy.[2] Medical treatment for prostatitis usually includes appropriate antimicrobial therapy. Finasteride therapy or castration should also be considered. Combination therapy with an antimicrobial and finasteride is more successful than treatment with an antimicrobial alone. Antimicrobial therapy should be based on bacterial sensitivity.

254.4 TESTICULAR PROBLEMS

254.4.1 Cryptorchidism

Cryptorchidism is the most common disorder of sexual development. It is defined as a lack of descent of one or both testes into the scrotum by 6 months of age.[8] In normal dogs, the testes usually have descended by 10 days of age. The incidence of cryptorchidism is higher in dogs (0.8% to 9.8%) than in cats (1.7%). The condition is more common in certain breeds (e.g., toy and miniature poodles, Yorkshire terriers, Chihuahuas, boxers, and miniature schnauzers). Cryptorchidism is considered a hereditary disorder, therefore an animal with this condition should not be used for breeding. The exact mode of inheritance is not known, but it is thought to be a sex-limited autosomal recessive type; therefore both males and females can carry the gene and pass it on to their offspring.

1694 1695

The diagnosis is made on the basis of the physical examination findings. In the cat, the penis should be examined for androgen-dependent penile spines (Figure 254-5).[2,20] The penile spines atrophy by 6 weeks after complete castration. (Retained testes are atrophic and are generally not visible on abdominal ultrasound scans.) An animal with unilateral cryptorchidism (one testis in the scrotum) dog can produce sperm, whereas dogs that are bilaterally cryptorchid usually do not produce sperm. Because cryptorchidism does not affect testosterone production, a cryptorchid animal would show sexual desire and may be able to breed.

Hormonal analysis is the definitive diagnostic test for differentiating bilaterally cryptorchid animals from castrated animals. Baseline serum testosterone concentrations of less than 0.02 ng/mL indicate an absence of retained testicular tissue. In dogs with abdominally retained testes, the serum testosterone concentration usually is 0.1 to 1.2 ng/mL, whereas in adult dogs with one or two scrotal testes, the serum testosterone concentration usually is 1 to 5 ng/mL. However, testosterone is secreted in pulses throughout the day, therefore challenge testing may be more accurate than evaluation of a single sample. A hormonal stimulation test with HCG or GnRH can be used to demonstrate the presence and production of testosterone.[2,20,21] The incidence of Sertoli cell tumors is higher with abdominally retained testes. Although not a common

occurrence, torsion of an abdominal testis can occur, leading to sudden abdominal pain. This phenomenon occurs almost exclusively in dogs with testicular tumors.

Treatment of animals with cryptorchidism is limited to castration. In unilaterally cryptorchid dogs, both testes (scrotal and abdominal) must be removed. Medical treatment with hormones such as GnRH or HCG is not effective. Removal of carrier parents from the breeding population would result in a decrease in the incidence of this condition.

254.4.2 Scrotal Hernia

With a scrotal hernia, the abdominal contents pass through the inguinal canal into the scrotum. An incidence of less than 1% is reported, and the condition occurs primarily in young dogs ranging in age from 5 months to 4 years (the average age is 1.73 years).[2]

Figure 254-5 Spines on the penis of a cat.

Figure 254-6 Unilateral left side enlargement of the scrotum of a 3-year-old pug with a hernia.

Differential diagnoses include orchitis, testicular torsion, testicular neoplasia, sperm granulomas, and trauma. On physical examination, a common finding is a fluctuant enlargement of the scrotum; in some cases, unilateral enlargement (Figure 254-6) is associated with ipsilateral inguinal swelling. The definitive diagnosis is made by careful palpation of the scrotum. Ultrasonography of the scrotum provides excellent information on the type of contents (Figure 254-7). Treatment involves surgical removal or replacement of the herniated tissues.

Figure 254-7 Sonogram of the scrotum with a hernia. Note the oval-shaped gray testis. The white areas below the testis are part of the omentum that has herniated from the abdomen. The black area around the testis is fluid, which accumulated in the scrotum. The hernia was corrected by surgery.

254.4.3 Testicular Tumors

Testicular tumors are common in dogs and rare in cats. The three most common types are Sertoli cell tumors, seminomas, and interstitial cell tumors. The reported incidence of testicular tumors is 0.91%, and the age of affected dogs ranges 2 to 19 years. The tumors may be unilateral or bilateral. All three types are equally prevalent in descended testes.

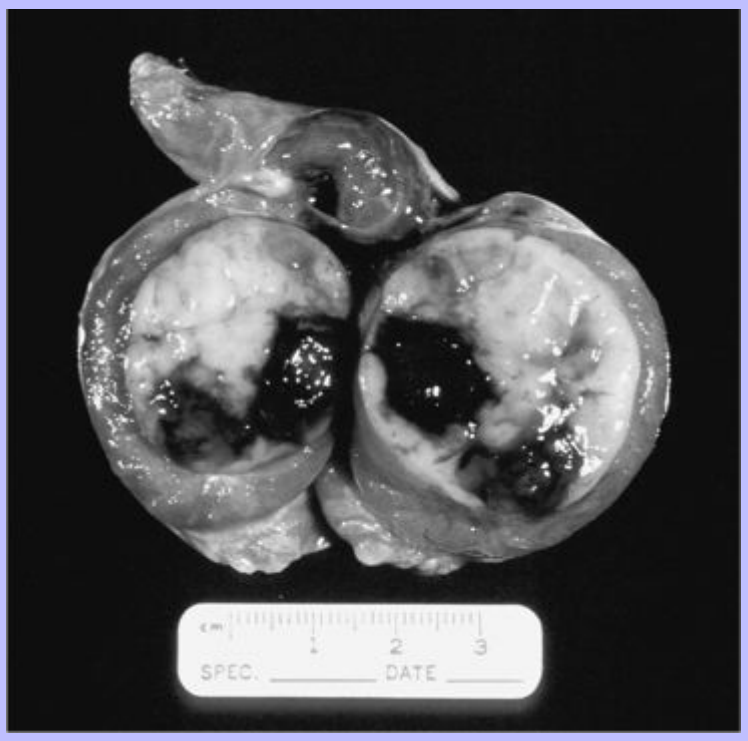
Dogs with testicular tumors most often have testicular enlargement without pain. A presumptive diagnosis is made by digital palpation and/or ultrasonographic examination of the scrotum. A neoplastic testis may or may not be significantly enlarged. Atrophy of the contralateral testis may have occurred as a result of hormone produced by the neoplastic testis or of an increase in the intrascrotal temperature. Nonpalpable tumors may be visualized sonographically, but the tumor type cannot be differentiated with this imaging modality.

Castration is the treatment of choice. Because of the high incidence of bilateral neoplasia and atrophy of the unaffected testis, removal of both testes is recommended. Unilateral orchiectomy may be considered in valuable breeding dogs. Sperm numbers decline 50% immediately after unilateral orchiectomy. Compensatory hypertrophy of the remaining testis, characterized by increased diameter of the seminiferous tubules, may be evident as early as 3 months after surgery.[2]

Sertoli cell tumors (SCTs) are more common in abdominally retained testicles. The scrotal testis that contains a SCT is usually enlarged and firm. Sonographically, the SCT is visible in the testicular parenchyma as a hypoechoic to anechoic area. SCTs commonly are associated with a feminizing paraneoplastic syndrome

caused by estrogen secretion, which may lead to estrogen-induced pancytopenia. Feminizing signs are reported in 24% to 39% of dogs with an SCT. The clinical signs of paraneoplastic syndrome include bilaterally symmetric alopecia of the trunk and flanks with hyperpigmentation of the inguinal skin; a dry, easily epilated coat; gynecomastia; a pendulous preputial sheath; attraction of male dogs; and bone marrow hypoplasia with nonregenerative anemia.[2] Signs of feminization resolve within 21 days of surgical removal of the SCT. The prognosis for dogs with bone marrow hypoplasia secondary to SCT is guarded. Exfoliated cytology of the preputial mucosa may be useful for confirming the presence or recurrence of hyperestrogenism in dogs with SCT. The epithelial cells show cornification similar to that seen in the vaginal cells of a bitch in estrus.

Figure 254-8 Testicular seminoma from an 8-year-old Dalmatian with an enlarged testis. Note the large areas of lobulated neoplasm and the areas of hemorrhage.



Seminomas (SEMs) are tumors of the spermatogenic cells. A higher incidence of these tumors is reported in older German shepherds (those over 10 years of age). Up to 10% of SEMs may metastasize to local or distant sites. Seminomas vary in size from 1 to 10 cm in diameter, are soft on palpation, and grossly are seen as homogenous or ovulated masses that are cream to pink-gray on the cut surface (Figure 254-8).

Interstitial (Leydig) cell tumors (ICTs), also called *interstitial cell adenomas,* arise from the endocrine cells of the testis. These tumors are small, usually less than 1 cm in diameter, and vary in color from yellow to brown on the cut surface. ICTs are the tumor of scrotal testes. Unlike the other two tumor types, ICTs are an incidental finding at the time of necropsy.

255 CHAPTER • 255 Feline Reproduction

Sophie A. Grundy

Autumn P. Davidson

255.1 REPRODUCTIVE TRACT ANATOMY

255.1.1 The Queen

255.1.1.1 Reproductive Tract

The reproductive tract of the queen is suspended in the abdominal cavity by the broad ligament, an extension of the peritoneum, which consists of the mesovarium, mesometrium, and the suspensory and proper ligaments of the ovary. The ovaries of the queen are mobile, oval, and typically 8 to 9 mm long.[1] The ovaries are attached cranially to the diaphragm by the suspensory ligament, which is attached to the abdominal wall by the mesovarium. The caudal pole of the ovary is attached to the tip of the uterine horn by the proper ligament. The lateral surface of the ovary is covered by an extension of the mesovarium, the mesosalpinx, and the medial surface is covered by the infundibulum of the uterine tube. The mesosalpinx in the queen is small and contains no fat, permitting excellent laparoscopic visualization of the ovary.

The uterine tube (oviduct) in the queen is 4 to 6 cm long and is visible as a tortuous structure within the mesosalpinx near the ovary. The uterus is bicornuate and extends from the uterine tubes cranially to the cervix caudally. The body of the uterus is 2 to 3 cm long, and each horn is 9 to 11 cm long and 0.3 to 0.4 cm wide. The mucous membrane of the uterus, which typically is reddish brown but may be focally pigmented (black), contains wide, spiral, longitudinal folds. Transabdominal palpation of the normal uterus and uterine horns typically is possible only during estrus or pregnancy.

The feline vestibule is 1 to 2 cm long, and the vagina is 2 to 3 cm long. The external urethral orifice is located ventrally at the vestibulovaginal junction. The feline cervix is approximately 45 mm cranial to the vulva. The cervix, vagina, and vestibule of the queen have a horizontal orientation. Examination of the cervix in the queen is difficult, because the vagina is narrower than the vestibule and nondistensible.[2] The intravaginal component of the cervix is papilliform and has the external uterine orifice. The queen has major mucous-producing vestibular glands (Bartholin's glands), 5 mm in diameter, in the lateral aspect of the vestibule.

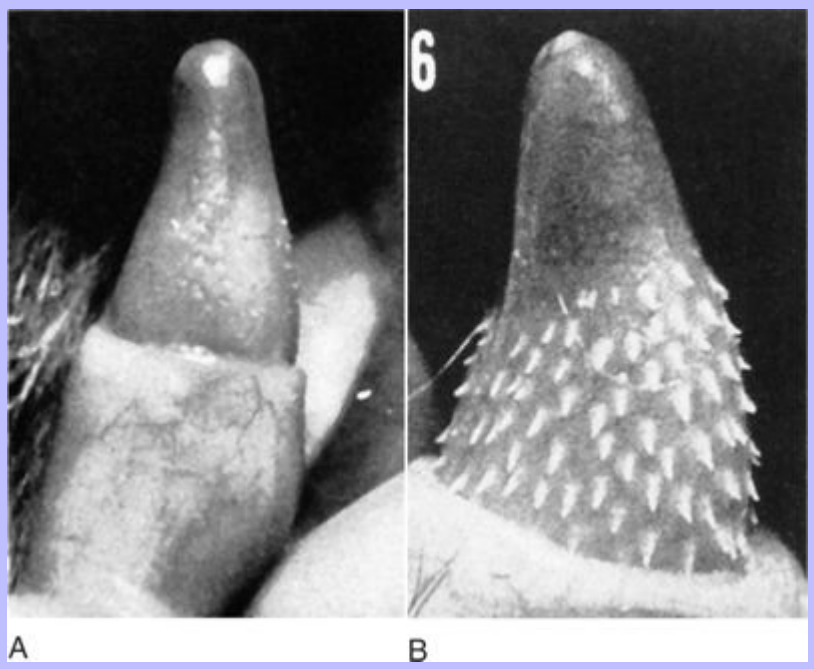
The vulva of the cat is covered with dense hair and does not vary during different stages of the estrous cycle because it is unresponsive to estrogen. The clitoris is small and protrudes slightly from the shallow fossa clitoridis; it is not normally visible.

255.1.1.2 Mammary Gland

The typical female cat has eight mammary glands arranged symmetrically in four pairs extending from the ventral thorax to the abdomen. The preferred nomenclature for glandular identification is numeric; from 1 to 4, left and right, with the cranial glands being numbered 1. Each mammary gland consists of multiple lobules drained by four to eight ducts, which open into each teat. The lymphatic drainage of the two caudal

teats is the superficial inguinal lymph node, whereas the two cranial mammary glands drain into the axillary lymph nodes. No lymphatic connections exist between the cranial and caudal segments of the mammary glands or across the midline, nor does lymphatic drainage from the mammary gland enter the abdomen or thorax.[3]

Figure 255-1 The smooth glands of a castrated male cat and penile spines of an intact male cat. (From Aronson LR, Cooper ML: Penile spines of the domestic cat: their endocrine behavior relations. Anat Rec 157:71–78, 1967.)



255.1.1.3 Placentation

Implantation occurs 12 to 13 days after ovulation in the cat. Fetuses are usually evenly distributed in the left and right horns as a result of embryo transmigration. The queen exhibits zonary, endotheliochorial placentation resulting from the loss of maternal endometrial epithelium and connective tissue. The fetal chorionic capillary epithelium is in direct contact with the maternal capillary endothelium, and placental transfer of maternal antibodies has been demonstrated in the queen.

255.1.2 The Tomcat

255.1.2.1 Reproductive Tract

The feline scrotum is ventral to the anus and lies dorsal to the caudally directed penis. The scrotum is densely covered with hair. The testes of the tomcat are ovoid to spherical and approximately 1.5 cm long

and are positioned obliquely so that the epididymis is craniodorsal.[4] The epididymis is not normally palpable because of its close attachment to the testes. The spermatic cord and the tubular tunica vaginalis, which covers it, are relatively long due to the distance between the scrotum and the superficial inguinal ring. The feline penis is structurally similar to the canine penis, having proximal cavernous and distal osseous components. The os penis is small (approximately 5 mm long) and is pointed distally. The prepuce is a thick fold with a caudally facing orifice. The penis is usually contained within the prepuce. The base of the penis is studded with six to eight rows of small, cornified, keratinized papilla (spines), which are present only under the influence of testosterone. Penile spines are considered a secondary sex characteristic in the domestic male cat (Figure 255-1).

The tomcat has two accessory sex glands, the prostate and the bulbourethral gland. The prostate of the tomcat is bilobed and consists of the pars compacta and the pars disseminata. The pars compacta, which is approximately 1 cm long, surrounds the dorsal and ventral urethra 2 to 3 cm caudal to the bladder. The pars disseminata consists of small lobules in the urethral wall extending from the bladder neck to the bulbourethral gland. The bulbourethral glands are small (5 mm long) and lie dorsolaterally on the urethra at the level of the ischiatic arch. 1697 1698

255.2 REPRODUCTIVE PHYSIOLOGY

255.2.1 The Queen

The queen is seasonally polyestrous. Ovarian activity is primarily under the influence of photoperiod and is stimulated by increasing hours of daylight. The true seasonal nature of the reproductive cycle of queens housed strictly indoors may not be evident. Cats maintained strictly indoors and exposed to artificial light for more than 14 hours a day may cycle at any time of the year and do not exhibit the typical seasonal breeding of their free-roaming counterparts. However, if these cats are returned to an outdoor environment, their ovarian activity becomes seasonal in nature. The queen exhibits induced, or reflex, ovulation. However, this is not an absolute phenomenon, and spontaneous ovulation occurs.[5]

255.2.1.1 Sexual Maturity and Pubertal Estrus

The queen typically reaches sexual maturity at 6 to 9 months of age. Two main factors influence the age of sexual maturity: body weight and exposure to light. The onset of ovarian activity and sexual maturity in the cat occurs as body weight approaches 2.5 kg; exposure to long photoperiod is essential. Queens exposed to outdoor light only typically exhibit estrus at the end of winter as day length increases. If a queen does not reach a body weight and age compatible with sexual maturity until late summer, when day length is decreasing, ovarian activity and sexual maturity most likely will be delayed until the following spring. The impact of breed on sexual maturity in domestic cats is small. As a general rule, oriental breeds are considered to exhibit pubertal estrus at an earlier age compared to long-haired breeds.

255.2.1.2 Estrous Cycle

In the absence of ovulation or pregnancy, repeated estrous cycles occur every 10 to 14 days during increasing photoperiod. The interval between repeated heat cycles is referred to as the *interestrous interval*. Other than the polyestrous cycle, which results in an interestrous interval, the queen has an estrous cycle that may be considered in four phases, which are similar to those in the dog: proestrus, estrus, diestrus, and anestrus.

Proestrus, the period of follicular development, is characterized by increasing serum estrogen concentrations. Queens do not permit mating during proestrus. The average duration of proestrus in the queen is 1 day. During this time, increased affection may be noted by the observant owner; however, proestrus is difficult to identify clinically. Under the influence of estrogen, the epithelial cells of the vaginal vault become cornified during proestrus and continue to cornify during estrus. In queens that permit vaginal cytology, vaginal smears may aid in the identification of proestrus.

Estrus, the period of sexual receptivity, is associated with follicle maturation and peak circulating serum concentrations of estrogen. In the queen, peak serum estrogen concentrations occur at the same time as maximal vaginal epithelial cornification. During estrus the queen permits copulation. The average duration of estrus in the queen is approximately 7 to 9 days regardless of coitus or ovulation.[6] There are few external physical signs of estrus in the queen. The female cat in estrus exhibits extreme affection, with a marked increase in head rubbing, vocalization, and frequent crouching of the thoracic limbs with rigid extension and treading of the pelvic limbs. Queens in estrus may also exhibit other signs, such as lordosis, and a laterally deviated tail. The presence of a male cat is not required to induce clinical signs of estrus. Queens subjected to stress may not exhibit behavioral estrus.

During copulation the male mounts the female and frequently bites the scruff of her neck. Male thrusting induces vocalization in the queen, which may be attributable to vaginal distention.[2] During the immediate postcoital period, the female exhibits a characteristic rolling and grooms the perineal region. Multiple copulations are common during estrus and may occur as frequently as every 15 to 20 minutes. The queen may exhibit mate preference towards particular tomcats.

After estrus the queen progresses through her estrous cycle, depending on the time of year, whether she experienced coitus, and her fertility. One of two outcomes follows estrus (Figure 255-2). One possible outcome is a nonovulatory cycle. Lack of ovulation typically occurs because of lack of copulation. If a queen does not ovulate, her estrous cycle will be 18 days long. This includes approximately 8 days of proestrus and estrus with a 10 day interestrous interval[5] (Figure 255-3). Anovulatory queens continue to exhibit signs of estrus every 18 days, providing they are exposed to increasing day length.

The other possible outcome is an ovulatory cycle. Estrogen priming of the reproductive tract is required to permit a surge in luteinizing hormone (LH) and ovulation in the queen. Historically, the release of gonadotropin hormone and ovulation in the cat were thought to occur only with stimulation of the vestibule and cervix associated with mating; however, spontaneous ovulation also occurs in the domestic cat.[2,5]

If the queen ovulates and forms functional corpora lutea, the rise in the serum progesterone concentration marks the start of *diestrus*. During diestrus, the serum estrogen concentration returns to baseline, and an increase in the serum progesterone concentration inhibits ovarian follicular development and return to estrus (Figure 255-4).

During an ovulatory nonpregnant cycle, the length of diestrus is determined by the life span of the corpora lutea. In the absence of pregnancy, the corpora lutea spontaneously regress after 35 to 37 days. At this time, the serum progesterone concentration returns to baseline, and the queen exhibits behavioral estrus approximately 10 days later. This results in an interestrous interval of about 45 days.

During an ovulatory pregnant cycle, the life span of the corpora lutea is prolonged and maintains the serum progesterone concentration above baseline for the duration of pregnancy. If the pregnancy is carried to term, gestation length is about 65 days. After queening, lactational anestrus typically delays the return to

heat for an additional 45 to 50 days. Lactational anestrus is caused by inhibition of the synthesis of gonadotropin-releasing hormone (GnRH) as a result of sensory input caused by suckling. The ovulatory pregnant interestrous interval in the queen is approximately 120 days if lactational anestrus occurs. Pregnancy loss after 35 days results in a variable interestrous length. Typically, signs of estrus are detected about a week after pregnancy loss.

The interestrous interval is defined as the interval between repeated heat cycles, during which the queen does not exhibit signs of estrus or permit coitus. In the absence of ovulation or pregnancy, the normal interestrous interval in the queen is approximately 10 to 14 days. At the end of the interestrous interval, the onset of behavioral estrus is associated with waves of ovarian follicular activity and increased estrogen production. Each estrus is not necessarily associated with a new follicular wave. Typically, during the interestrous interval, the serum estrogen concentration returns to baseline, and the subsequent estrous behavior is associated with a new follicular wave. However, in some cats, follicular waves may overlap, or the serum estrogen level may not return to baseline during the interestrous interval. Clinically, these individuals are identified by persistent behavioral estrus, prolonged estrus, or "nymphomania." This phenomenon is neither typical nor abnormal.

Figure 255-2 Flow diagram depicting the possible outcomes after behavioral estrus in the queen.

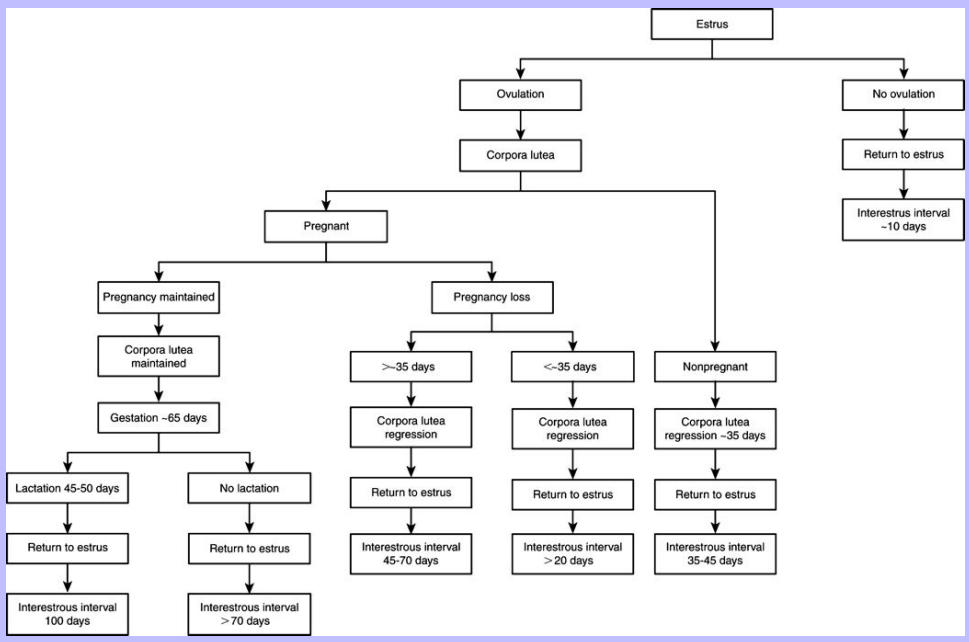

Figure 255-3 Schematic representation of the various estrogen secretion patterns that may occur during the estrous cycle of the cat. (From Feldman EC, Nelson R [eds]: Canine and Feline Endocrinology and Reproduction, 3rd ed. WB Saunders, 2001, pp 744 and 992.)

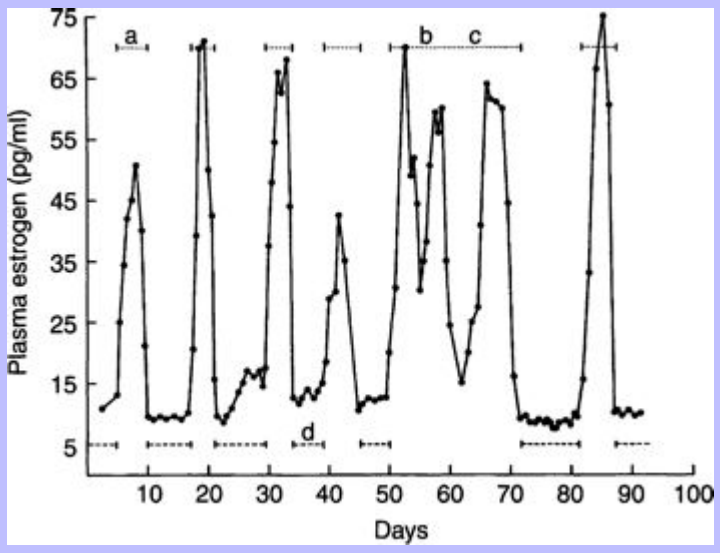
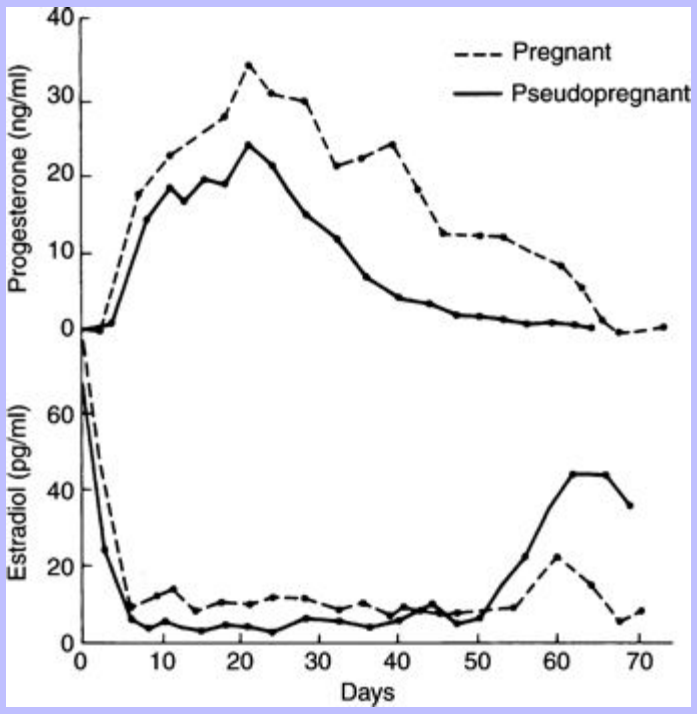


Anestrus is a time of ovarian quiescence, when there is no ovarian follicular activity or functional corpora lutea (CL). In the queen, anestrus occurs in association with a short photoperiod, when females are exposed to less than 4 to 6 hours of light per day. Outdoor queens typically enter anestrus during winter. Indoor queens may exhibit anestrus when exposed to less than 6 hours of light per day. Anestrus also results from exposure to continuous light due to ovarian hyperstimulation.

Figure 255-4 Average concentrations of progesterone and estrogen during ovulatory cycles in the queen. (From Feldman EC, Nelson R [eds]: Canine and Feline Endocrinology and Reproduction, 3rd ed. WB Saunders, 2001, pp 744 and 992.)



255.2.1.2.1 Hormone profile of the queen's reproductive cycle

Increased photoperiod is associated with decreased circulating plasma concentrations of melatonin in the queen. Serum prolactin and melatonin concentrations are thought to fluctuate in association with one another. The exact relationship between the serum prolactin and melatonin concentrations and ovarian activity is not well understood; however, during periods of ovarian activity (estrus), serum concentrations of both are low.[7]

Estradiol 17-beta is produced in association with the follicular phase of the ovarian cycle by the developing follicles. The serum estrogen concentration peaks during estrus, often exceeding 80 pg/mL. In the absence of ovulation, ovarian follicles regress, and the serum estrogen concentration typically decreases to baseline (less than 20 pg/mL) during the interestrous interval. As a new follicular wave develops, the cycle continues until cessation of the breeding season or induction of ovulation.

Induction of ovulation in the queen has historically been attributed to vaginal stimulation causing an LH surge. The amplitude and duration of each LH surge are influenced by the intensity and frequency of coital stimulation. An optimal LH surge is reported in association with four copulations within a 2-to 4-hour period. In some instances spontaneous ovulation occurs.

If ovulation occurs, the resulting corpora lutea induce an increase in the serum progesterone concentration within 24 to 48 hours. The serum progesterone level during diestrus may be as high as 60 ng/mL. In the nonpregnant female, the feline corpora lutea exhibit spontaneous regression after 35 to 37 days. A decline in the serum progesterone concentration is noted around day 25, with a return to baseline by day 40. In the pregnant animal, unknown mechanisms result in maintenance of the corpora lutea, with the serum progesterone concentration remaining greater than 2 ng/mL for the duration of gestation. The specific factors responsible for luteotropic support in the cat are unknown, but they may be associated with placental development, fetal development, or other, unidentified factors.

The serum relaxin concentration is detectable only in the pregnant queen. In early pregnancy (until day 25 of gestation), the serum concentration is low. Peak concentration (7 to 9 ng/mL) is reached around day 35 of gestation. During the last 15 days of gestation, a decline is noted, and the serum relaxin concentration is undetectable 24 hours prior to parturition.[8]

In the pregnant queen, the serum prolactin concentration begins to increase at day 35 of gestation and peaks prior to parturition. Prolactin is luteotropic in the pregnant queen and is the hormone responsible for mammary development and lactation. Administration of a dopamine agonist (e.g., cabergoline) results in a decrease in serum prolactin and a decline in serum progesterone. Serum prolactin concentrations are low during estrus.

255.2.1.2.2 Vaginal cytology during the estrous cycle

Vaginal cytology samples from the cranial vagina may be difficult to obtain in the conscious queen using a cotton tip applicator due to the narrowness of the vaginal vault. As an alternative, a small volume of saline (0.5 mL) can be flushed into and aspirated from the vagina to harvest vaginal epithelial cells. Vaginal cytology varies during the estrous cycle of the queen. During proestrus, the increasing serum estrogen concentration is reflected by an increase in the percentage of cornified vaginal epithelial cells. As queens enter estrus, mucous secretions thin, and debris is less visible in the background of vaginal smears; this is referred to as *clearing*.

An increase in keratinized anuclear squames is also noted on vaginal cytology during estrus in the queen.[7] Vaginal cytology during the interestrous interval is characterized by the predominance of nucleated superficial and intermediate squamous epithelial cells. The diestrus smear in the cat has a predominance of parabasal cells. During anestrus, vaginal cytology is similar to that during the interestrous interval, with a predominance of nucleated superficial and intermediate epithelial cells and much background debris.[7] Red blood cells are not noted during any phase of the reproductive cycle. Clinically, vaginal cytology in the queen may be used to detect the influence of estrogen in queens that fail to exhibit behavioral estrus or in those suspected of having ovarian remnant syndrome. Vaginal cytology is not a useful adjunct for ovulation timing in the queen nor is it useful for determining queening dates.

255.2.2 The Tomcat

The reproductive life span of the tomcat is reported to be more than a decade. In the absence of routine semen evaluation, information about reproductive performance is limited to litter production. Early declines in ejaculate quality typically remain undetected.

255.2.2.1 Sexual Maturity

Although spermatozoa may be evident in the spermatic cord of tomcats as early as 30 weeks of age, sexual maturity and the ability to mount, complete penile intromission, and ejaculate is rare prior to 12 months of age. Tomcats are typically sexually mature by 24 months of age. Persian and British breeds may mature later (3 years of age). Early characteristics associated with the development of sexual maturity in the tomcat include development of a rounded face and the onset of fighting, marking and mounting behaviors. Testicular descent is usually complete prior to birth. Spermatogenesis occurs in association with testicular weights greater than 1 g as body weight approaches 3 kg. The tomcat is capable of spermatogenesis year round; however, there is evidence of seasonal variation in sperm production and increased spermatozoa concentrations during long photoperiods.

255.2.2.2 Hormonal Profile of the Tomcat

The basal serum testosterone concentration in the intact male cat varies as a result of the pulsatile nature of the release of LH and follicle-stimulating hormone (FSH) from the pituitary. The serum testosterone concentration is an unreliable indicator of testicular function. In the domestic cat, penile spines develop under the influence of testosterone and provide a clinically useful bioassay for detection of circulating testosterone.

255.3 COMMON CLINICAL PROBLEMS

255.3.1 The Queen

255.3.1.1 Abnormal or Prolonged Estrous Behavior

Estrous behavior in a previously ovariohysterectomized female cat may indicate the presence of ovarian remnant syndrome. Alternatively, abnormalities of the zona reticularis of the adrenal cortex may be associated with sex hormone production. Ultrasonographic examination of the abdomen and evaluation of the serum sex hormone concentrations, along with stimulation of adrenocorticotrophic hormone (ACTH), may be useful for distinguishing between the two syndromes. Abnormal adrenal sex hormone production in the queen is uncommon.

255.3.1.2 Ovarian Remnant Syndrome

Ovarian remnant syndrome is the presence of functional ovarian tissue in a previously ovariohysterectomized animal. Functional residual ovarian tissue may produce enough follicular activity to trigger clinical signs of estrus in a female cat that had undergone ovariohysterectomy (OHE). Clinical signs of estrus generally occur months to years after OHE but can begin days after the surgery. The residual ovarian tissue is typically not in an abnormal location, and there appears to be no predisposition for the left or right ovary.[9] Accessory ovaries have been reported, but failure to remove ovarian tissue that extends into the mesovarium is more likely. Revascularization of free-floating ovarian tissue has been reported.[10]

The diagnosis of ovarian remnant syndrome is based on observation of appropriate clinical signs and confirmation of the presence of functional ovarian tissue through measurement of the serum estradiol

and/or progesterone levels. A serum estradiol concentration greater than 20 pg/mL is associated with clinical signs of estrus. Vaginal cytology is an inexpensive, convenient bioassay that can confirm the influence of estrogen (i.e., cornification of the vaginal epithelium). Provided that no adrenal pathology exists and that exogenous estrogens are not being administered, ovarian remnant syndrome is the most likely cause of cyclic estrous behavior in a cat thought to have been surgically neutered. Various techniques for confirming the presence of ovarian tissue through the use of GnRH or HCG have been described; however, this is seldom clinically justified.[11] An increased serum progesterone level (greater than 2 ng/mL measured 2 to 3 weeks after estrus) may be seen in association with luteinization of ovarian remnants.

Removal of residual ovarian tissue by exploratory celiotomy is curative. Surgery is recommended during estrus or diestrus, because the presence of ovarian follicles or corpora lutea aids the identification of residual ovarian tissue. Medical suppression of follicular ovarian activity with progestational or androgenic compounds is less desirable because of the side effects, such as diabetes mellitus.

255.3.1.3 Mucometra and Pyometra

Mucometra and pyometra may occur in the queen in association with cystic-endometrial hyperplasia or as separate clinical entities. Under the influence of progesterone, the intrauterine leukocyte response is suppressed, myometrial contractility is reduced, and endometrial gland development is stimulated. Uterine quiescence and endometrial gland secretions create an opportune environment for bacterial proliferation. Intrauterine bacterial contamination may occur via ascending the urogenital tract or by the hematogenous route, resulting in a pyometra. Alternatively, the uterus may become distended with mucus and may remain sterile, resulting in a mucometra. *E. coli* is the most common intrauterine bacterial isolate in feline pyometra. Exogenous progesterone administration and repeated heat cycles without pregnancy precipitate the development of pyometra.

The clinical signs associated with pyometra in the queen vary with cervical patency. Most queens with pyometra are ill at the time of examination, having clinical signs ranging from anorexia, lethargy, and weight loss to those of septic shock and peritonitis resulting from uterine rupture. Queens with an open-cervix pyometra typically exhibit a moist perineum and purulent vaginal discharge, and owners may report increased grooming behavior. Polyuria and polydipsia may be noted in association with open and closed pyometra as a result of the nephrogenic diabetes insipidus that occurs secondary to the effect of *E. coli* endotoxins on renal antidiuretic hormone (ADH) receptors.

Clinicopathologic evaluation most often reveals a neutrophilic leukocytosis and hyperglobulinemia. Hypoalbuminemia may be noted in association with sepsis, and a decreased blood urea nitrogen (BUN) may be noted with severe polyuria and polydipsia. The serum progesterone concentration at the time of diagnosis typically is greater than 5 ng/mL. Vaginal cytology is unreliable for the diagnosis of pyometra. 1701
However, cytologic specimens containing numerous degenerate neutrophils with intracellular bacteria are 1702
consistent with pyometra. Ultrasonographic evaluation of the uterine horns is a reliable method of diagnosing pyometra. The uterine lumen is typically distended with flocculent material of variable echogenicity (Figure 255-5). Cystic ovarian structures may be noted, but the ultrasonographic appearance of the ovary varies.

The treatment of choice for pyometra is medical stabilization with antimicrobials and intravenous fluids, followed by surgical ovariohysterectomy. Medical therapy with natural prostaglandins and antimicrobials may be considered for queens with mucometra or for some cats with pyometra. Successful treatment of mucometra and pyometra with prostaglandin$_2$-α (PGF_2-α) (Lutalyse; Pharmacia and Upjohn, Kalamazoo,

Michigan) results from the drug's effect on the uterine myometrium, cervix, and corpora lutea. In the queen, the corpus luteum is relatively resistant to the effects of exogenous prostaglandins. Repeated measurement of the serum progesterone concentration is advised prior to and during prostaglandin therapy to identify animals with persistent luteal function. Medical therapy should be considered only if an animal is of reproductive importance. Candidates for medical PGF_2-α therapy should be young (less than 6 years of age) and otherwise healthy, with evidence of a patent cervix (i.e., vaginal discharge). Contraindications for medical management of pyometra or mucometra include sepsis, peritonitis, significant organ disease, or old age, which is associated with an increased incidence of cystic endometrial hyperplasia. Concurrent administration of bactericidal broad-spectrum antimicrobials is advised.

PGF_2-α should be administered subcutaneously at a dosage of 0.1 mg/kg twice a day for 2 days, and increased to 0.2 mg/kg twice a day until abdominal ultrasound scans reveal no evidence of uterine enlargement, the complete blood count (CBC) has normalized, polyuria has improved, and the serum progesterone level is less than 5 ng/mL. Synthetic prostaglandins are available for use in Europe, and the dosage must be adjusted to account for the variation in potency. Side effects of prostaglandin therapy include restlessness, emesis, salivation, tenesmus, diarrhea, lordosis, and kneading. Administration of the prostaglandin at a reduced dosage for the first 48 hours should reduce the severity of side effects. Breeding at the next estrous cycle is recommended.

255.3.1.4 Pregnancy Termination

Please refer to Chapter 250.

255.3.1.5 Abnormal Mammary Development not Associated with Pregnancy

Mammary development in a nonpregnant or spayed female is abnormal. Care must be taken to distinguish between mammary development, which typically involves more than one gland, and formation of a

mammary mass. Mammary development occasionally may occur in male or female cats in association with cessation of exogenous progestogen administration; however, the degree of mammary development is usually mild and transient.

In comparison, mammary hyperplasia (also known as *fibroadenomatous mammary hyperplasia*) is associated with dramatic enlargement of multiple mammary glands (Figure 255-6). The glands typically are painless, but they may become necrotic and subject to secondary infection. Usually no milk production occurs in these glands. Mammary hyperplasia is most frequently noted in young animals after their first estrous cycle. The condition appears to be associated with an increase in the serum progesterone concentration, and antiprogestins may be indicated.[12] Surgical mastectomy is indicated with severe necrosis or infection.

255.3.1.6 Mammary Masses

Mammary tumors are the third most common neoplasia in cats. Early ovariohysterectomy is associated with a decreased risk of mammary neoplasia. Most feline mammary tumors are malignant, and carcinomas are the most common tumor type.[13] Any detected mammary mass in the feline should be surgically removed with wide margins by an experienced surgeon and considered malignant until proven otherwise. Prior to surgical excision, ultrasonographic evaluation of the regional lymph nodes and radiographic evaluation of the thorax are advised to detect metastatic disease.
